The extensor carpi radialis (ECR) muscle is the largest extensor muscle of the forelimb and has a prominent muscle belly on the cranial aspect of the antebrachium. The ECR muscle extends the carpus, smoothes carpal joint movement by dampening oscillations as the hoof strikes the ground, and flexes the elbow.^{1,2} The extensor carpi radialis tendon (ECRT) extends through most of the muscle belly and appears on the surface of the muscle in the middle of the antebrachium. The tendon passes through the middle groove at the distal end of the radius, over the dorsal aspect of the carpus, and inserts on the metacarpal tuberosity on the dorsal proximal aspect of the third metacarpal bone.¹ As the tendon passes over the carpus, it is bound by the extensor retinaculum and enveloped by a synovial sheath, which extends from 8 to 10 cm proximal

to the carpus, to the level of the middle carpal joint. Distal to the sheath the ECRT is attached to the carpometacarpal joint capsule. There is usually a small bursa beneath the tendon at the level of the third carpal bone.^{1,3}

The common digital extensor (CDE) muscle is a compound muscle with three heads (humeral, radial, and ulnar) that lies lateral to the ECR muscle on the craniolateral aspect of the radius and acts to extend the digit and carpal joints and to flex the elbow. The main common digital extensor tendon (CDET) appears on the surface of the muscle in the middle of the antebrachium and passes distally through the lateral groove on the cranial distal aspect of the radius and over the capsule of the carpal joints. As the tendon passes distally over the dorsal aspect of the metacarpal region, it courses medially and reaches the dorsal midline just proximal to the fetlock. At the level of the distal aspect of the proximal phalanx the tendon becomes wider as it is joined by extensor branches of the interosseous tendon (suspensory ligament). The CDET inserts on the extensor process of the distal phalanx and the dorsal surface of the proximal extremities of the proximal and middle phalanges.

The CDET is enveloped by a synovial sheath as it passes over the carpus. The sheath extends from about 8 cm proximal to the carpus to the proximal end of the metacarpal region.^{1,3} A bursa is present between the tendon and the dorsal pouch of the fetlock joint capsule.^{1,3,4}

A small tendon also arises from the smaller head (the radial head) of the CDE muscle. This tendon runs through the synovial sheath of the principal tendon and then passes laterally to fuse with the lateral digital extensor tendon (LDET) or may continue separately between the CDET and LDET to the fetlock. A small tendon may also arise from the ulnar head of the CDE muscle, which either fuses with the principal tendon or inserts on the joint capsule dorsal to the fetlock joint.

The lateral digital extensor (LDE) muscle is smaller than the other extensor muscles and is situated caudal to the CDE muscle. The action of the LDE muscle is to extend the digit and carpus. The LDET arises at the level of the distal third of the antebrachium and passes distally through the groove on the lateral styloid process of the radius and over the lateral aspect of the carpus. The tendon becomes larger and flattens distal to the carpus as it joins the tendon of the radial head of the CDE muscle and a strong band from the accessory carpal bone. The LDET runs lateral to the CDET and gradually inclines toward the dorsal aspect of the metacarpal region and inserts on the eminence on the dorsal proximal aspect of the proximal phalanx.¹

A synovial sheath envelops the LDET as it passes over the carpus. It begins 6 to 8 cm proximal to the carpus and extends to the proximal end of the metacarpal region.^{1,3} At the fetlock a small bursa lies between the tendon and the joint capsule.¹

The extensor carpi obliquus is a small muscle that extends the carpus. The tendon of the extensor carpi obliquus arises at the distal end of the radius and courses distally, cranially, and medially over the ECRT and then passes through the oblique groove at the distal end of the radius to insert on the base (head) of the second metacarpal bone. The tendon is enveloped by a synovial sheath.¹

In the hindlimb, the long digital extensor (LoDE) muscle is situated superficially on the craniolateral aspect of the limb and acts to extend the digit and flex the hock. The tendon of the muscle begins in the middle of the muscle belly and passes distally over the dorsal aspect of the hock, where the tendon is bound by the extensor retinacula and enveloped by a synovial sheath. The sheath extends from slightly proximal to the level of the lateral malleolus of the tibia to the proximal third of the metatarsal region. The long digital extensor tendon (LoDET) is joined by the LDET about 10 cm distal to the tarsus. In the angle of this union the extensor digitorum brevis also joins the principal tendon of the LoDE.¹ Distal to this point the arrangement of tendons is the same as in the forelimb.

The LDE muscle lies on the lateral surface of the crus caudal to the LoDE muscle. The LDET runs through the entire length of the muscle belly and emerges at the level of the distal third of the tibia. The tendon descends through the groove on the lateral malleolus of the tibia, where it is bound by the extensor retinacula, and usually blends with the LoDET. In some horses the tendon does not insert on the LoDET but passes separately lateral to the LoDET and inserts on the eminence on the dorsal proximal aspect of the proximal phalanx, like the corresponding tendon in the forelimb.¹ The tendon is surrounded by a synovial sheath that extends from 4 to 6 cm above the lateral malleolus of the tibia to the proximal third of the metatarsal region.^{1,3}

DIAGNOSTIC TECHNIQUES

Many disorders of the extensor tendons, particularly acute injuries, may be diagnosed by careful clinical examination, gait analysis, and palpation. Diagnostic perineural or intrathecal analgesia may be useful in horses with chronic injuries to the extensor tendons to determine the importance of clinical findings. Synoviocentesis of distended tendon

sheaths or bursae also may be helpful to distinguish between tenosynovitis caused by injury or infection.

Plain radiography is of little value in identifying soft tissue injuries of the extensor tendons unless radiodense foreign material or bone fragments are present. Radiology may be useful to evaluate mineralization within the tendons or the synovial sheaths, enthesopathy, and associated osseous abnormalities. Contrast radiography may demonstrate a penetrating tract, intrathecal adhesions, or synovial fistulae between the extensor tendon sheaths and carpal joints.^{5,6}

Ultrasonography is a safe, noninvasive method of evaluating the extensor tendons, the synovial sheaths, and the bursae. A 7.5- or 10-MHz transducer and standoff pad are used to image the extensor tendons and the respective tendon sheaths. Careful evaluation of transverse and longitudinal images allows the clinician to determine the extent of tendon damage, the presence of foreign bodies within the tendon or tendon sheaths, synovial membrane hyperplasia, and intrathecal adhesions.⁷

CONDITIONS AFFECTING THE EXTENSOR TENDONS

Laceration of the Digital Extensor Tendons

Lacerations of the extensor tendons commonly occur in the metacarpal or metatarsal regions of the limbs because of their superficial location at these sites (see Chapter 81). Extensor tendon lacerations are more common in the hindlimb⁸⁻¹¹ and are frequently associated with considerable soft tissue damage and opening of the extensor tendon sheaths.

Transection of an extensor tendon below the carpus or tarsus leads to reduced ability to extend the digit, which results in an exaggerated, rapid flip of the hoof at the end of the swing phase of the stride, intermittent knuckling over at the fetlock, or tripping at the walk. The horse, however, will bear weight in a normal posture if the foot is placed flat on the ground. This gait abnormality is more obvious in horses with hindlimb injuries and when the laceration is near the fetlock because remaining peritendinous fascial attachments provide some support to the distal part of the tendon in more proximal injuries.

Lacerations with transection of the extensor tendons proximal to the carpus, and at or just proximal to the tarsus, are also common. Transection of the CDET and ECRT commonly occurs proximal to the carpus and often results in pain on flexion of the carpus. Transection of the LoDET proximal to or at the tarsus results in greater tarsal flexion during the swing phase of the stride and intermittent knuckling of the digit. Within a few days of transection of an extensor tendon the horse learns to adapt its gait, and tripping and knuckling of the fetlock become less frequent.

The diagnosis of extensor tendon laceration is often apparent from the gait deficit. If necessary, the diagnosis may be confirmed by exploration of the wound with a sterile, gloved finger after aseptic preparation and wound lavage. Plain and contrast radiography should be used to evaluate concomitant joint or bone damage and to help to identify foreign bodies.

After aseptic preparation, wounds over the extensor tendons should be debrided and lavaged. It is important to

debride any exposed or obviously devitalized bone and, where possible, to cover bone with skin to reduce the risk of sequestrum formation. Primary apposition of the lacerated tendon is unnecessary even if a large gap has formed between the distracted tendon ends. Progressive ultrasonographic evaluations show that fibrous tissue develops between the transected tendon ends; this tissue gradually becomes more organized and regains the linear arrangement of collagen along the line of the original tendon. This fibrous tissue provides an adequate mechanical link between the tendon ends, allowing extensor function of the digit to return.¹²

Although lacerations of extensor tendons may heal without external coaptation, wound healing is facilitated and exuberant granulation tissue formation is controlled if limb immobilization is used during the first 3 to 6 weeks after injury. Immobilization may be achieved using a polyvinylchloride (PVC) splint or cast. Full-limb PVC splints may be applied to the dorsal or palmar aspect of the forelimb to prevent knuckling of the fetlock and carpal flexion. In the hindlimb, a distal limb splint applied to the dorsal or plantar aspect of the limb can be used. Application of a shoe with a toe extension may help facilitate flat foot placement and prevent tripping or knuckling over of the fetlock in the early postinjury period. Casts provide an inexpensive and efficient means of immobilizing the limb and tendon ends and are especially useful when extensor tendon lacerations occur with extensive, contaminated wounds, in which primary wound closure cannot be achieved.

After removal of the cast or splint, the horse should remain confined to a box stall for another 4 to 6 weeks. During this period the toe should be trimmed short so that it does not catch to cause knuckling and disruption of the organizing fibrous tissue. A controlled exercise program of in-hand walking exercise may be initiated at this time to strengthen the tendon and improve gliding function. Passive range of movement exercises may also be beneficial. If no signs of knuckling are present after 10 to 12 weeks of controlled exercise, a gradual return to athletic use may begin.

The prognosis for return to athletic function after extensor laceration is good.⁸⁻¹¹ In a retrospective study of 156 horses with extensor tendon lacerations, 74% returned to soundness and 60% of sports horses returned to previous activity at the same, or higher, level.¹⁰ In this study there was a significant influence on positive outcome if primary closure of the wound was performed, with horses 2.6 times more likely to return to soundness compared with those horses in which wound closure was not performed. Complications in that study included wound infection and dehiscence, exuberant granulation tissue, and sequestrum formation. Stringhalt may also occur as a complication of lacerations or injury to the extensor tendons in the dorso-proximal aspect of the metatarsal region. It is speculated that stringhalt may result from adhesion formation, which decreases the ability of the long or LDETs to stretch during hock flexion, or from abnormalities in the myotatic reflex, which governs extensor muscle tone and relaxation.¹³

Rupture of the Common Digital Extensor Tendon

Rupture of the CDET occurs in foals and may be present at birth or may develop within the first few weeks of life. This

Fig. 77-1 • Fluctuant swelling over the dorsolateral aspect of the carpus in a foal with rupture of the common digital extensor tendon (CDET). The injury shows the typical transverse depression in the sheath where the CDET has ruptured (*solid arrow*) and the bulge in the sheath where the transected distal part of the tendon is situated (*open arrow*).

condition may be primary or secondary to flexural deformities of the carpus or metacarpophalangeal joint that result in increased tension in the CDET.¹⁴ Rupture of the CDET may be an inherited condition because Arabians and Quarter Horses were overrepresented in one retrospective study.¹⁵

As rupture of the CDET always occurs within the synovial sheath,¹⁴ affected foals have a characteristic fluctuant swelling over the dorsolateral aspect of the carpus at the level of the distal carpal joints (Figure 77-1). Palpation reveals fluid distention of the tendon sheath, and the ruptured ends of the CDET can usually be identified. Affected foals may have a normal stance but often stand with the carpus slightly flexed (over-at-the-knee appearance) and frequently knuckle forward on the fetlock. Most affected foals, however, quickly accommodate the gait and learn to flip the distal aspect of the limb during the swing phase of the stride.

Diagnosis of rupture of the CDET is based on careful palpation and is confirmed by ultrasonography. Radiography of the carpus should be performed to rule out cuboidal bone malformation.

In foals with primary injuries without associated flexural deformities, treatment usually involves box rest and the application of well-padded bandages to support the carpus and prevent abrasion of the dorsum of the fetlock.

In foals that exhibit frequent knuckling over on the fetlock, or foals with concurrent flexural deformities of the carpus, a PVC splint should be applied to the palmar aspect of the limb, extending from the elbow to the fetlock. For foals with concurrent cuboidal bone malformation, tube casts from the elbow to the fetlock should be used to provide carpal support. Foals with splints usually walk comfortably, and sufficient fibrosis has usually developed after 2 to 4 weeks to allow removal of the splints. However, the foal should be maintained in padded bandages for several more weeks to maintain pressure on the area of tendon rupture to minimize the resultant blemish.

It has been suggested that the ruptured ends of the CDET are unlikely to reunite but adhere to the tendon sheath and that the LDET assumes the function of the CDET.¹⁵ However, anecdotal evidence indicates that the tendon ends may rejoin in some horses.¹⁶ Consequently, foals with primary rupture of the CDET, without concurrent cuboidal bone malformation, usually have an excellent prognosis for athletic performance with minimal blemish. Foals with concurrent cuboidal bone malformation or flexural deformities have a more guarded prognosis for athletic performance.^{17,18}

RUPTURE OF THE EXTENSOR CARPI RADIALIS TENDON

Rupture of the ECRT is a rare condition of adult horses.¹⁵ Partial rupture may also occur rarely, particularly in horses that are used for jumping.¹⁹ Complete and partial rupture of the ECRT usually occurs within the synovial sheath on the dorsal aspect of the carpus. The injury is believed to result from trauma associated with repeated overflexion of the carpus.¹⁵ Partial rupture of the ECRT was reported to be a consequence of tendon damage caused by exostoses on the distal aspect of the radius.¹⁹

Acute rupture of the ECRT is characterized by pain and distention of the tendon sheath. Extension and flexion of the carpus are limited, which may result in dragging of the toe.²⁰ In horses with chronic injuries of the ECRT, distention of the tendon sheath persists but is usually painless unless an associated inflammatory tenosynovitis occurs.

Complete rupture of the ECRT results in excessive carpal flexion during limb protraction and consequently a higher arc of foot flight in the affected limb. Limb extension may be characterized by a double movement as the carpus suddenly snaps into extension.^{21,22} Atrophy of the ECR muscle may be evident in horses with chronic injuries. Partial rupture of the ECRT may be associated with mild lameness and restricted carpal flexion.¹⁹

Diagnosis of rupture of the ECRT may be confirmed by careful palpation, ultrasonography, and contrast radiography.^{6,7} Plain radiography should be used to evaluate associated osseous lesions.

Horses with acute, complete rupture of the ECRT may be treated surgically. Tenosynovectomy with primary suturing of the tendon ends, or substitution of the extensor carpi obliquus tendon by tendon anastomosis, has been described.¹⁵ Other authors, however, believe that surgical apposition of the tendon ends is unnecessary and advocate tenoscopy, which allows characterization of the extent of the injury, debridement of the damaged tendon ends, and lavage of the sheath. After surgery the limb should be

immobilized in a tube cast or splint for 2 to 4 weeks. Once the cast and sutures have been removed, passive range-of-movement exercises should be instituted to prevent the formation of intrathecal adhesions and to reduce carpal joint capsule fibrosis, which result in a limited range of carpal flexion. The prognosis for return to athletic performance for horses with complete rupture of the ECRT is unfavorable. The prognosis for return to athletic performance for horses with partial rupture of the ECRT is guarded to fair, but tenolysis and partial tenosynovectomy may benefit some horses.^{15,20}

Trauma to the Extensor Carpi Radialis Tendon

Single episode trauma, such as a kick injury, or repetitive trauma from hitting fixed cross-country fences or pawing at a door, may result in a primary injury of the ECRT, often accompanied by tenosynovitis, with or without adhesion formation between the tendon and tendon sheath. Such injuries may be accompanied by new bone formation on the distal aspect of the radius. The ECRT is usually palpably enlarged, with associated distention of the tendon sheath. Ultrasonographic examination confirms enlargement of the tendon and determines the extent of injury to the tendon and the presence of adhesion formation. Although horses with mild injuries often respond well to medical management, those with severe injuries may require en bloc surgical removal of the injured tendon and the synovial lining of the tendon sheath. Cosmetic results are often poor, but the prognosis for athletic function is reasonable.

Enthesopathy of the Insertion of the Extensor Carpi Radialis Tendon

In the racing Standardbred, tearing of the ECRT attachment at its insertion on the proximodorsal aspect of the third metacarpal bone can cause lameness, and these tears may play a role in the cause of fractures of the dorsomedial aspect of the proximal end of the third metacarpal bone (see Chapter 37).²³

CONDITIONS AFFECTING THE EXTENSOR TENDON SHEATHS

Tenosynovitis

Idiopathic Tenosynovitis

Idiopathic tenosynovitis may be defined as swelling with synovial effusion but without active inflammation, pain, or lameness.¹⁵ Idiopathic tenosynovitis of the extensor tendon sheaths has been reported in foals at birth.²⁴ In adults the condition tends to develop insidiously. The pathogenesis in newborn foals is unknown, but in adult horses the pathogenesis is presumed to be caused by chronic trauma.¹⁵ However, distention of the LoDE sheath in hindlimbs often occurs bilaterally, is unassociated with any history of trauma, and is of unknown cause.

Ultrasonographic examination usually reveals anechoic fluid within the sheath. Occasionally, hypoechoic lesions are identified within the enclosed tendon, the clinical significance of which is unknown because lameness is rarely present.

As idiopathic tenosynovitis usually is not associated with pain or lameness, treatment is unnecessary unless the

owner is concerned about cosmesis. Treatment by injection of corticosteroids (10 to 20 mg triamcinolone acetonide or 40 to 80 mg methylprednisolone acetate) and pressure bandaging often only provides a temporary resolution of tendon sheath effusion.¹⁵ Anecdotal reports suggest that intrathecal injection of 4 to 15 mg of atropine sulfate, alone or with corticosteroids and hyaluronan, may cause permanent resolution of the effusion. Atropine sulfate is purported to reduce the production of synovial fluid from synoviocytes; however, its anticholinergic effects mean that its use has been associated with transient signs of mild colic and depression. The Editors have never recognized any side effects of intrathecal injection of atropine.

Acute Traumatic Tenosynovitis

Acute tenosynovitis is characterized by a rapidly developing effusion of a tendon sheath, accompanied by heat, pain, and variable lameness. Acute tenosynovitis of the extensor tendon sheaths is often caused by trauma, such as a fall or hitting a jump with the carpus.¹⁹ This injury is common in event horses, in which it often is not associated with lameness.¹⁶

Diagnosis of acute tenosynovitis is based on clinical signs and ultrasonography. Ultrasonography is useful to evaluate concurrent tendonitis of the extensor tendons and to differentiate acute tenosynovitis from other conditions that are associated with soft tissue swelling over the dorsal aspect of the carpus, including hygroma, cellulitis, synovial hernia, and effusion of the carpal joints (see Chapter 38).

Horses with acute tenosynovitis of an extensor tendon sheath are treated by rest, cold hydrotherapy, and nonsteroidal antiinflammatory drugs (NSAIDs). Aspiration of fluid and injection of corticosteroids are reserved for horses that do not respond to more than 1 week of conservative treatment.²⁵

Infectious Tenosynovitis

Infectious tenosynovitis is characterized by dramatic synovial effusion, heat, pain, swelling, and severe lameness. Contamination from a penetrating wound is the most common cause of infectious tenosynovitis, but infection also may arise from hematogenous spread of bacteria and iatrogenic infection.²⁶ Infection of the CDET sheath has been reported as a complication of hemicircumferential periosteal transection.²⁷ After penetration of a tendon sheath, severe lameness does not become evident unless infection becomes established. If the tendon sheath is open and draining, then the lameness may be less severe.²⁸

Once infection is established, rapid and aggressive treatment is necessary to prevent synovial hyperplasia, fibrosis of the tendon sheath, intrathecal adhesion formation, and damage to the extensor tendons. Prompt recognition of infectious tenosynovitis is essential for a successful outcome. Diagnosis of infectious tenosynovitis is based on clinical signs and must be confirmed by synovial fluid aspiration and analysis. Infected synovial fluid is typically turbid and has a low viscosity, an elevated total nucleated cell count ($>30 \times 10^9/L$, with more than 90% neutrophils), and a total protein concentration of more than 40 g/L. Contrast radiography (Figure 77-2) or ultrasonography may be useful to confirm a communication between a penetrating wound and the tendon sheath, especially if horses are examined soon after injury.

Fig. 77-2 • Lateromedial radiographic image of a carpus. Dorsal is to the left. Positive-contrast medium has been injected into the extensor carpi radialis tendon sheath and antebrachio-carpal joint in a horse that had sustained a deep puncture wound over the dorsal aspect of the carpus. Radiopaque contrast agent is present near the skin surface (solid arrow), outside the tendon sheath (small arrows), confirming penetration of the extensor carpi radialis sheath. The antebrachio-carpal joint (open arrow) was not involved.

The primary aim of treatment of horses with infectious tenosynovitis is the rapid elimination of bacteria and rapid return of the normal synovial environment. This is best achieved by wound debridement, lavage of the tendon sheath with copious amounts of sterile isotonic fluids, and the provision of bactericidal levels of appropriate antibiotics within the sheath.

Appropriate systemic and intrathecal antibiotic therapy should be initiated immediately. The presence of *Enterobacteriaceae* most commonly is associated with tendon sheath infection caused by a penetrating wound, whereas staphylococci are most commonly identified as the cause of iatrogenic infections of a tendon sheath.²⁶ The most effective combination of antibiotics for the treatment of infectious tenosynovitis is amikacin and cephalosporin (>85% effective).²⁹ However, the cost of these drugs may be prohibitive, and other drug combinations, such as penicillin and gentamicin, may be considered. The initial selection of antibiotic should be altered according to bacterial susceptibility if a positive culture is obtained from the synovial fluid.

Wound debridement and lavage of the affected tendon sheath with copious amounts of sterile isotonic fluids are important to reduce concentrations of bacteria and inflammatory mediators. Early in the infection, effective lavage may be achieved by through-and-through lavage using

large-bore needles or arthroscopic egress cannulas. In more established infectious tenosynovitis, leukocytes and fibrin accumulate within the sheath, necessitating tenoscopic debridement. If satisfactory debridement and lavage have been achieved, primary closure of the sheath may be performed. The horse should be monitored closely for lameness, and repeated synovial fluid samples should be taken at 2- to 3-day intervals to monitor for return of infection. Alternatively the sheath may be left open, or a closed suction drain system may be inserted into the sheath for further elimination of inflammatory mediators and fibrin. The drain should be left in place for 3 to 5 days, but careful management is important to prevent ascending suprainfection.

Systemic antibiotic therapy should be continued for at least 2 weeks after the resolution of clinical signs. Once the infection has been eliminated, intrathecal injection of corticosteroids or hyaluronan may be used, with physiotherapy, to reduce adhesion formation and restore the normal gliding movement of the tendon within its sheath. However, both drugs may cause immunosuppression within the sheath and may potentiate dormant infection. Early return to controlled exercise is also important to reduce intrathecal adhesion formation.

If chronic infectious tenosynovitis becomes established, exploration of the tendon sheath and radical synovectomy may be required (see the following discussion). Successful outcomes have been reported after complete resection of the intrasynovial part of the CDET in horses with chronic infectious tenosynovitis and tendonitis.^{30,31}

The prognosis for return to soundness after infectious extensor tenosynovitis is more favorable than for infectious flexor tenosynovitis,^{26,28} possibly because extensor tendons are non-weight bearing compared with flexor tendons. The prognosis for return to soundness is generally good after early surgical intervention and appropriate antibiotic therapy for horses with infectious extensor tenosynovitis.

Chronic Tenosynovitis

Chronic tenosynovitis of the extensor tendon sheaths is characterized by persistent synovial effusion, fibrous thickening of the sheath, and subcutaneous edema.^{32,33} Chronic tenosynovitis results in variable, sometimes severe, lameness, restricted carpal flexion, and a gait characterized by circumduction of the affected limb during protraction.³³ However, in some horses there is no gait abnormality.

Chronic tenosynovitis commonly arises after penetrating injuries to the carpal extensor sheaths, which may result in the inoculation of foreign material or bacteria into the synovial cavity and establishment of an infectious or noninfectious chronic tenosynovitis. The condition commonly occurs in horses jumping natural fences because of penetration of the sheath by thorns.³³ Chronic tenosynovitis also may occur after acute tenosynovitis and may be associated with partial tendon rupture.^{22,32} Chronic inflammation of the tendon sheath causes granulomatous proliferation of the synovium, connective tissue deposition in the fibrous capsule, and fibrous adhesion formation between the tendon and its sheath, resulting in restriction of movement and pain on carpal flexion.^{32,33}

Diagnosis of chronic tenosynovitis is based on clinical signs of effusion and thickening of the affected sheath (Figure 77-3) and restricted carpal flexion. Radiography of the carpus often reveals palisading new bone formation on

Fig. 77-3 • Chronic distention of the tendon sheath of the extensor carpi radialis in a horse with chronic tenosynovitis.

the craniodistal ridges of the radius adjacent to the affected sheaths (Figure 77-4) and enthesioid new bone formation on the dorsal aspect of the carpal bones.³³ Synovial fluid aspirates vary from serosanguineous to turbid, with an increased nucleated cell count and total protein concentration. Ultrasonography may demonstrate tendon damage, synovial hypertrophy, foreign bodies, and intrathecal adhesions.

Conservative treatment with antibiotics, analgesics, intrathecal corticosteroids, and symptomatic physiotherapeutic procedures such as bandaging, cold hosing, massage, and forced exercise is usually unrewarding.^{19,22,32,33} Good results, however, have been reported after both tenoscopic and open surgical intervention.^{19,33,34} Tenoscopic examination of the sheaths of the ECRT, CDET, and LDET allows radical synovectomy of the hyperplastic synovium, removal of intrathecal adhesions, and debridement of damaged tendon and is associated with a good prognosis for resolution of lameness. The cosmetic appearance of most distended extensor tendon sheaths after tenoscopic surgery can be substantially improved, although most have some residual fibrosis.³⁴ The prognosis for soundness after open surgical exploration and radical synovectomy has been reported to be good,³³ although the resultant scar may cause a substantial blemish. After surgery, an intensive program of physiotherapy involving manual flexion and extension of the carpus and an ascending program of in-hand walking exercise should be initiated. Early passive motion to stimulate cavitation and reformation of the synovial lining and prevent adhesion formation is considered an essential part of the treatment.³³ Initially, carpal flexion is resented, and administration of NSAIDs and sedatives may be required.

Fig. 77-4 • A craniolateral-caudomedial oblique radiographic image of the distal aspect of the radius in a horse with chronic tenosynovitis of the extensor carpi radialis tendon sheath. There is palisading new bone formation (arrows) on the craniomediodistal ridge of the radius adjacent to the tendon sheath.

Full flexion of the carpus should be achieved by 30 days after surgery.

Osteochondromatosis

Synovial osteochondromatosis of the ECRT sheath has been reported.³⁵ Synovial osteochondromatosis is characterized by the formation of multiple small osseous bodies within a synovial-lined structure. The cause is unclear but it may be associated with trauma. Clinical signs include swelling on the dorsal surface of the carpus characterized by multiple, firm subcutaneous nodules and crepitus during joint movement, and lameness is usually evident. Diagnosis is confirmed by radiography and ultrasonography.³⁵ No information is available for the surgical treatment of osteochondromatosis of the extensor tendon sheaths in horses, but partial synovectomy and endoscopic removal of the osteochondral bodies was successful in other synovial cavities in horses and other species.³⁶

Intersynovial Fistulae

Intersynovial fistulae are uncommon, but they have been documented between the CDET sheath and antebrachio-carpal joint,³⁷ the CDET sheath and middle carpal joint,¹⁵ and the ECRT sheath and middle carpal joint.⁵ The cause of these fistulae is unclear, but they are considered to be traumatic in origin and may occur in horses with carpalitis or carpal fractures.^{5,37} Typically, horses with intersynovial fistulae have chronic lameness and distention of the affected tendon sheath. Synovial fluid can be massaged from the joint to the tendon sheath. Diagnosis may be confirmed by contrast radiography⁶ and intrasynovial analgesia. Surgical treatment is advocated in the management of intersynovial fistulae,¹⁵ but little information concerning

Fig. 77-5 • Prominent soft tissue swelling over the dorsal aspect of the fetlock region in the hindlimb of a horse with severe lameness. This is a supratendonous infectious bursitis and should not be confused with infectious arthritis of the metatarsophalangeal joint. Arthrocentesis of the metatarsophalangeal joint through a dorsal approach may result in iatrogenic infectious arthritis.

the prognosis of affected horses is available because reports of this condition are rare. Use of tenoscopic approaches to close fistulae between the carpal joints and extensor tendon sheaths has been largely unsuccessful.³⁴ Surgical treatment involving a combination of endoscopically assisted synovectomy and limited open exposure of the fistula, and closure of the fibrous layers of the joint and tendon sheath are generally recommended.³⁴

Infectious Bursitis

Infectious bursitis may occur in any of the bursae associated with the extensor tendons over the dorsal aspect of the fetlock. The condition is seen most commonly in horses that jump natural obstacles (e.g., event and National Hunt horses). Typically these horses have swelling over the dorsal aspect of the fetlock (Figure 77-5) and mild-to-severe lameness. Infectious bursitis may affect the subtendonous bursae or more commonly affects an acquired subcutaneous (supratendonous) bursa on the dorsal aspect of the LoDET in the fetlock region.³⁸ Occasionally both bursae may communicate around the lateral or medial aspect of the LoDET. Some horses have a severe, non-weight-bearing lameness. This condition frequently is confused with infectious arthritis of the metacarpophalangeal or metatarsophalangeal joints. Diagnosis is confirmed by ultrasonographic examination or contrast radiography⁶ and synoviocentesis. Synoviocentesis from the palmar or plantar pouch of the adjacent metacarpophalangeal or metatarsophalangeal joint should be used to rule out joint infection. Treatment consists of surgical drainage and debridement and appropriate antimicrobial therapy. The prognosis for return to soundness is good.

Chapter 78

Curb

Mike W. Ross and Ronald L. Genovese

References
on page
1320

The historical definition of *curb* is enlargement on the plantar aspect of the fibular tarsal bone (calcaneus) caused by inflammation and thickening of the (long) plantar ligament.¹ There is confusion regarding the cause of curb; a seminal publication uses this historical definition in the text but describes curb as superficial digital flexor (SDF) tendonitis in a figure legend.² By ultrasonographic evaluation curb was redefined as a complex of soft tissue injuries that occurs on the distal plantar aspect of the tarsus.^{3,4} Long plantar (LP) desmitis is only one of many injuries that causes curb. However, the indelible term *curb* has been used for hundreds of years⁵ and is still useful to describe swelling of the distal, plantar aspect of the tarsus (excluding the calcaneal bursa and proximal aspect of the calcaneus). In the rest of this chapter, *curb* is used specifically to mean the clinically apparent soft tissue swelling of the plantar aspect of the tarsus seen best from the side. Conformational abnormalities or bony exostoses can mimic or contribute eventually to formation of curb.

CLINICAL APPEARANCE OF CURB

The convex profile typical of curb is best seen from the side (Figure 78-1). Careful evaluation of swelling from all perspectives, palpation, and thorough lameness examination are critical. Curb must be differentiated from other swellings of the hock, including capped hock, effusion, edema and fibrosis of the calcaneal bursa (see Chapter 79), tarsal tenosynovitis (see Chapter 76), thoroughpin (with or without involvement of the tarsal sheath), and bony enlargements of the distal hock region (see Chapter 44). Injuries of the deep digital flexor tendon (DDFT) as it courses along the plantaromedial aspect of the hock within the tarsal sheath can produce typical signs of curb, but they account for only a small percentage of injuries in horses with curb.

Horses with sickle-hocked conformation are said to be *curby* (see Chapter 4). Sickle-hocked and in-at-the-hock conformation lead directly to curb, a finding most common in Standardbred (STB) and Thoroughbred (TB) racehorses. Prognosis for STB racehorses with sickle-hocked conformation and curb is worse in a trotter than in a pacer. Trotters with sickle-hocked conformation are usually fast early in training and racing, but this conformation is often career limiting. Sickle-hocked conformation is also undesirable in TB racehorses. Horses with sickle-hocked conformation often develop curb first, but they then independently or concomitantly develop other lameness associated with the distal hock joints. Tarsal region lameness begins with curb in 2- and 3-year-olds and progresses to osteoarthritis of the centrodistal and tarsometatarsal joints or slab fractures of the central tarsal bone, or more commonly the third tarsal bone.

Horses can have curby conformation without developing curb, and horses with normal hindlimb conformation can develop curb. The proximal aspect of the fourth metatarsal bone (MtIV) is often prominent in horses with sickle-hocked conformation. The most dramatic example of altered joint morphology occurs in young foals with tarsal crush syndrome, the result of delayed or incomplete ossification of the tarsal cuboidal bones (see Chapter 44).

Firm, fibrous soft tissue swelling can develop just proximal to the MtIV as a sequela to injection or local analgesia of the tarsometatarsal joint, presumably from local trauma, hemorrhage, or leakage into the subcutaneous tissues. Mild bony proliferation or fragmentation of the proximal aspect of the MtIV, or of the fourth tarsal bone, can cause focal swelling easily mistaken for curb.

Considerable variation in clinical signs occurs, and the injury cannot be categorized, or a management program and prognosis established, without thorough clinical and ultrasonographic examinations. Historically, owners and trainers consider curb to be an annoying, self-limiting problem that rarely causes lameness or poor performance, that responds to a single treatment that is uniformly effective, and that is cured by treatment. Most racehorse trainers are opposed to resting a horse with curb unless lameness is performance limiting, so veterinarians often are faced with management decisions without an option for even short-term rest or a reduction in training intensity. Many traditional therapies have no data to support efficacy. Thus, progress in understanding and management of this complex soft tissue injury has been limited.

Fig. 78-1 • A Standardbred racehorse with typically appearing curb. Swelling associated with the distal, plantar aspect of the tarsus is centered over the centrodistal and tarsometatarsal joints. In this horse swelling was caused by superficial digital flexor tendonitis.

Lameness ranges from none, mild, or severe depending on the structure involved and extent of injury. Lameness tends to be worse if the soft tissue structure involved is located dorsal to the superficial digital flexor tendon (SDFT) in the plantar aspect of the tarsus (i.e., the DDFT and/or the long plantar ligament [LPL]), if SDFT injury is diffuse, or if a mixed injury involves more than one structure. Diagnosis is straightforward in horses with obvious lameness seen at a trot in hand and painful swelling, but lameness may be evident only as a slight loss of performance or unlevelness when the horse is performing maximally and may be perceived only by trainers, drivers, or riders. A horse with chronic curb may not exhibit signs of pain during palpation, or lameness at a trot in hand, but can show lameness at speed, and convincing a trainer that the long-term swelling is a source of pain may be difficult. The area should be palpated carefully with the limb bearing weight and flexed. Swelling may be firm and fibrous, with few signs of active inflammation, or may be warm, painful, and edematous. Acute, compliant, or mushy swelling is associated with hemorrhage or other subcutaneous fluid accumulation and sometimes deeper soft tissue injury. Horses with this form of curb usually have acute, moderate-to-severe lameness. Horses with distal hock joint pain often exhibit a painful response when direct pressure is placed on plantar hock structures, including the SDFT, proximal aspect of the MtIV, second metatarsal bone, and proximal aspect of the suspensory ligament. Often swelling is not detected in these horses. Response to upper limb flexion varies and is nonspecific. Direct digital palpation followed by trotting is useful, because horses with active inflammation show increased lameness.

Because horses with curb can have concomitant osteoarthritis or other problems of the distal hock joints, differentiation of the source of pain is important but difficult. Diagnostic analgesia is useful but not foolproof. If horses

are lame at a trot in hand, local infiltration of local anesthetic solution subcutaneously over the curb is effective. A minimum of 20 to 30 mL of local anesthetic solution should be infiltrated along the lateral, plantar, and medial aspects of the curb. Small-gauge needles should be avoided (to avoid needle breakage), and the injection should be performed with the limb in flexion, because horses may object to several injections. If horses are not visibly lame at a trot in hand, examination at the track or under saddle should be performed. Selective intraarticular analgesia of the distal hock joints and sequential perineural analgesia to rule out the lower limb are essential. A tibial nerve block alleviates pain with curb, but it is seldom done because other common sources of pain are abolished similarly.

Radiography and scintigraphy help differentiate other sources of pain, but ultrasonography is the imaging method of choice to determine which structures are involved and the extent of damage.

APPLIED ANATOMY AND NORMAL ULTRASONOGRAPHIC EXAMINATION OF THE PLANTAR ASPECT OF THE TARSUS

Plantar to the calcaneus are skin, subcutaneous tissues, a thin fibrous tissue layer, the SDFT, and the LPL (Figure 78-2). Medially the DDFT courses distally over the sustentaculum tali, within the tarsal sheath. Normally the tarsal sheath has a small amount of fluid that can be seen during ultrasonographic examination, but it is not felt. The LPL originates from the calcaneus, closely adheres to this bone, and inserts distally on the plantar surface of the fourth tarsal bone and the MtIV. The plantar aspect of the tarsus can be divided into zones to classify findings (Figure 78-3) or the distance measured from the proximal aspect of the

Fig. 78-2 • A, Cross-section of the left tarsus at the level of zone 1A (lateral is to the right and plantar is uppermost). At this level the superficial digital flexor tendon (SDFT) and long plantar ligament (LPL) are located on the plantar aspect of the calcaneus, and ultrasonographic examination of these structures is completed with the transducer on the plantar midline. For imaging of the deep digital flexor tendon (DDFT), the transducer must be positioned plantaromedially. In this specimen from a normal horse the thin peritendonous and periligamentous tissue (arrow) layer can be seen. **B**, Cross-section of the left tarsus distal to the section shown in **A** at the level of zone 1B2 (same orientation as **A**). Note that the LPL is now located plantarolaterally; for accurate anatomical and cross-sectional data information regarding the LPL to be obtained, an ultrasound transducer must be placed along the plantarolateral aspect of the limb (black arrow). At this level the DDFT is located plantaromedially, and for accurate depiction of this structure ultrasonographically the transducer must be placed on the plantaromedial aspect of the limb (arrow).

Fig. 78-3 • The plantar aspect of the tarsus is divided into zones 1A and 1B. Because zone 1B is rather large and important, the zone is sometimes subdivided into 1B1 and 1B2. An alternative technique for recording level of injury is to measure distally from the proximal aspect of the calcaneus.

calcaneus (point of hock). Swelling comprising curb occurs in zone 1 of the tarsal and metatarsal regions but can extend into zone 2 if SDF tendonitis occurs. Transverse and longitudinal images of both limbs should be obtained from the plantar midline, plantaromedial (to evaluate the DDFT), and slightly plantarolateral (to evaluate the distal aspect of the LPL). Measurement of cross-sectional area (CSA) is important to confirm lesions in which enlargement has occurred but with no overt fiber damage. Precise placement of the ultrasound transducer is important because the LPL changes size and shape as it courses distally. Knowledge of normal ultrasonographic anatomy is crucial (Figures 78-4 to 78-7).^{3,4}

CURB: A COLLECTION OF SOFT TISSUE INJURIES³

One hundred and ten horses with curb were examined using ultrasonography, including 87 (79%) racehorses (72 STB and 15 TB) and 23 nonracehorse sports horses (six field or show hunters, six Western performance horses, four show jumpers, two event horses, two gaited horses, two horses of unknown use, and one dressage horse).³ Mean and median ages (range 1 to 13 years) were 3.4 and 3.0, respectively. There were 32 late yearlings or 2-year-old horses, of which all were STBs; 24 of these STBs were examined before or near the time of a qualifying race. There were 24 intact males, 35 females, and 51 geldings. No sex predilection was found. Curb occurred in the left hindlimb (LH) in 60 horses, right hindlimb (RH) in 37 horses, and bilaterally in 13 horses. Of the 13 horses with bilateral curb, 11 were STBs. Within STBs there were 61 pacers and 11 trotters, compared with an expected population (ratio of pacers:trotters is 3:1 in North America) of 54 pacers:18

Fig. 78-4 • Transverse (left) and longitudinal (right) midline ultrasonographic images at 8 cm distal to the point of the hock. A thin subcutaneous fibrous tissue layer runs along the plantar surface of the superficial digital flexor tendon (SDFT) (double-headed arrow). The SDFT (crescent-shaped) is narrower in a medial-to-lateral direction and somewhat thickened compared with further proximally. In the longitudinal scan the normal SDFT has a dense parallel fiber pattern. Deep to the SDFT the long plantar ligament (LPL) is at full thickness (plantar-to-dorsal direction), is rectangular, and is attached firmly to the calcaneus (CAL). At this level the deep digital flexor tendon is out of view medially and must be evaluated by placing the transducer plantaromedially.

Fig. 78-5 • Transverse (left) and longitudinal (right) ultrasonographic images from the plantaromedial aspect of the left hock 5 cm distal to the point of the hock. In the transverse image the tarsal sheath surrounds the deep digital flexor tendon (DDFT). The tendon is oval and has a large eccentric hypoechoic region composed of residual muscle tissue, but this defect could be caused by incident angle artifact.

trotters. Curb was thought to result from excessive stress or strain from race training (80 horses), direct trauma (11 horses), previous injection (three horses), associated injuries (three horses), and an apparent “bad step” or unknown cause (13 horses). The most common reported form of direct trauma was stall or wall kicking. Curb was the primary reason for examination in 94 horses, was a compensatory lameness in 10 horses, and was seen in association with other tarsal injury or ipsilateral hindlimb lameness in six horses. Sixty-three horses were lame, and although lameness score was not uniformly recorded in the

Fig. 78-6 • Transverse (left) (medial is to the right) and longitudinal (proximal is to the left) (right) plantarolateral ultrasonographic images 9 cm distal to the point of the hock at the level of the fourth tarsal bone (T4). The long plantar ligament (PL) is a multiseptated structure, and large plantar fiber bundles are not normally perfectly aligned with dorsal bundles. In transverse images the PL normally may appear to lack echogenicity, and the size and shape change at the insertion on the fourth tarsal bone. The PL is wide at the insertion on the fourth tarsal bone (longitudinal scan).

Fig. 78-7 • Transverse (left) (medial is to the left) and longitudinal (right) (proximal is to the right) plantarolateral ultrasonographic images 12 cm distal to the point of the hock, just distal to the insertion of the long plantar ligament (LPL) on the fourth tarsal bone (T4). The LPL is thick in the plantar-to-dorsal direction. A midline image would show the superficial digital flexor tendon and deep digital flexor tendon, but at this level a plantarolateral transducer placement is needed to assess the LPL. In the transverse image the normal heterogeneous fiber pattern of the LPL and cross-sectional area measurement can be seen. In the longitudinal image the LPL is seen attaching to the fourth metatarsal bone (MtIV) distally.

medical record, recorded lameness scores ranged from 1 to 2 out of 5. Horses with LP desmitis, those with SDF tendonitis extending distally from zone 1 into zone 2 of the proximal metatarsal region, those with deep digital flexor (DDF) tendonitis, and those with combined soft tissue injuries exhibited most pronounced lameness. Swelling (prominence of curb) was pronounced in horses with recent or combined soft tissue injury and in those with hematoma or abscess formation in the peritendinous and periligamentous (PT-PL) tissue. Swelling was described as fibrous in nature in many horses, particularly in STBs in which curb was chronic and in horses in which previous management

Fig. 78-8 • Transverse midline ultrasonographic image (medial is to the left) of the plantar aspect of the hock of 2-year-old Standardbred gelding obtained in zone 1B. There is subcutaneous edema (arrows) and thickening. The superficial digital flexor tendon (SDFT), deep digital flexor tendon (DDFT), and long plantar ligament (PL) were normal. This horse was managed using a peritendinous injection of corticosteroids.

Fig. 78-9 • Transverse (left) (medial is to the left) and longitudinal ultrasonographic images of zone 1B2 of the right hock in a 2-year-old trotter with curb. Thickening and mild fluid accumulation in the peritendinous and periligamentous tissues (double-headed arrow) are present, but the underlying soft tissue structures are normal. In the longitudinal image the plantar swelling giving the clinical profile associated with curb can distinctly be seen.

included cryotherapy, topical counterirritation, or thermocautery. However, in acute injuries the swelling was often edematous, warm, and painful on palpation.

Ultrasonographic diagnosis included peritendinous-periligamentous (PT-PL) swelling without injury of the SDFT, DDFT, and LPL (29 [26%] horses) (Figures 78-8 to 78-10), PT-PL swelling primarily consisting of hematoma (six horses), and PT-PL swelling primarily consisting of abscess formation (five horses). Overall, 40 (36%) horses had swelling confined to the PT-PL tissues without other underlying soft tissue injury. There were 32 (29%) horses with PT-PL swelling and SDF tendonitis (Figure 78-11); 25 horses with PT-PL and LP desmitis (Figure 78-12); five horses with LP desmitis alone; five horses with DDF tendonitis; complex tarsal soft tissue injury of the LPL, PT-PL tissues, and gastrocnemius tendon in two horses; and tarsocrural collateral desmitis in one horse. Overall, only 32 (29%) horses had involvement of the LPL.

Management and outcome in these 110 horses with curb were difficult to assess, and information in medical

Fig. 78-10 • Transverse (left) (medial is to the right) and longitudinal midline ultrasonographic images of the hock in zone 1B in a 5-year-old Thoroughbred racehorse. There is soft tissue swelling of heterogeneous echogenicity of the peritendonous and periligamentous tissues and fibrous adhesion (double-headed arrow) plantaromedial to the superficial digital flexor tendon (SDFT). The SDFT, deep digital flexor tendon (DDFT), and long plantar ligament (PL) are normal.

Fig. 78-11 • Transverse (left) and longitudinal midline ultrasonographic images of the plantar aspect of the hock of 2-year-old Standardbred racehorse with curb resulting from peritendonous and periligamentous tissue injury and superficial digital flexor tendonitis. Subcutaneous fibrous tissue accumulation (top arrow) plantar to the superficial digital flexor tendon (SDFT) and a central anechoic lesion of the SDFT can be seen, findings verified in the longitudinal view. Cross-sectional area of the affected superficial digital flexor tendon was 33% greater than that of the contralateral normal tendon.

records was lacking. There was a tendency for clinicians to manage horses with curb that were not lame or those in which curb was a compensatory issue with subcutaneous injections of a corticosteroid-containing preparation in combination with a reduction in exercise intensity or a short period of rest. Most of these horses had PT-PL swelling. Horses in which curb caused actual lameness were generally managed with rest and nonsteroidal antiinflammatory drug (NSAID) administration, but cryotherapy and

Fig. 78-12 • Transverse plantarolateral ultrasonographic images of the left hindlimb (LH) (abnormal) and right hindlimb (RH) (normal) plantar tarsi in zone 1B of 3-year-old Standardbred pacer. The left long plantar ligament (PL) is enlarged, with an indistinct central hypoechoic lesion. DDFT, Deep digital flexor tendon; SDFT, superficial digital flexor tendon.

topical counterirritation were often performed as well. Horses with severe SDF tendonitis extending into zone 2, LP desmitis, DDF tendonitis, or combination soft tissue injury were given long-term rest (>3 months) and controlled return to exercise, but they were the group most likely to do poorly or to remain lame. Horses (five) with PT-PL swelling and abscessation had surgical drainage and appropriate antimicrobial therapy and successfully returned to exercise. Associated ipsilateral lameness conditions included osteoarthritis of the centrodistal and tarsometatarsal joints and metatarsophalangeal joint pain.

Curb was previously described as simply LP desmitis,^{1,2,5} but is a collection of plantar tarsal soft tissue injuries. In fact, in 68% of horses with curb in this study, the LPL was normal ultrasonographically, and horses with curb were more likely to have injury of the PT-PL tissue alone or in combination with SDF tendonitis than injury of the LPL.³ Curb should not be used synonymously with LP desmitis. Although not directly studied, CSA measurement (see Figure 78-7) of all soft tissue structures should routinely be performed and compared with measurements from the contralateral limb (some horses are bilaterally affected), because common forms of SDF tendonitis and LP desmitis are often associated with increased CSAs rather than frank fiber tearing.

Curb is primarily an injury of racehorses, especially STBs. Gait, speed, and training methods differ between racing breeds, and STB racehorses have a higher prevalence of conformational abnormalities, such as sickle-hocked and in-at-the-hock conformation. These conformational abnormalities have not been directly studied, and a cause-and-effect relationship is therefore difficult to establish. However, sickle-hocked conformation may increase load on the distal plantar soft tissue structures, predisposing to curb. Weight and load distribution are considerably different in STBs and TBs. Curb develops frequently in STB racehorses that train and race on a thin, near-hard surface, contrary to many soft tissue injuries that result from work on deep surfaces. Many curbs develop in young STB

racehorses early in training when they are jogging and not formally performing speed work. In some instances track surfaces are inconsistent and perhaps slippery, because early training is done in the winter months. In many horses clinical signs are recurrent and progressive, and the development of clinical signs early in training supports a theory that curb develops primarily as a result of overload of plantar soft tissue structures, in a roughly plantar-to-dorsal direction, because the most common tissue involved is the PT-PL tissues. For instance, in our study SDF tendonitis was not seen in horses without PT-PL tissue enlargement, suggesting that PT-PL injury may have preceded injury of the SDFT.³ Pronounced lameness in horses with SDF tendonitis was seen only when injury progressed distally into zone 2 in the proximal metatarsal region; in some horses sickle-hocked conformation and alleged loss of support of the hock produced what appeared as a dropped hock. Horses with this form of curb, LP desmitis, or combination injury are most likely to be lame. Curb was more common in the LH limb, and although it is tempting to associate this finding with counterclockwise training, many horses developed curb before speed work commenced in that direction. Perhaps in STBs the conventional practice of giving horses many slow miles of jogging in a clockwise direction may place additional load on the outside LH, predisposing to curb. Curb appears more common in pacers than trotters. Nonracehorse sports horses develop curb, but only sporadically, and lameness is often moderate to severe and most commonly is associated with PT-PL tissue swelling, although other structures are sometimes involved.

Peritendonous and Periligamentous Inflammation

PT-PL tissue swelling occurs alone or with abnormalities of one or more of the SDFT, DDFT, or LPL. PT-PL tissue injury can occur secondary to direct trauma from horses kicking a wall or trailer door, or rarely from a direct kick or interference injury from another horse, resulting in acute, large, painful swelling. Ultrasonographic examination most often reveals frank hemorrhage and edema. More commonly the horse has neither a history of trauma nor clinical findings suggesting trauma. We suspect that PT-PL tissue injury reflects excess loading or strain of the plantar tarsal soft tissue structures from race training. Extensive jogging of young STBs early in training may cause dramatic increase in hock loading, and tension and overstretching of thin PT-PL tissue occurs. PT-PL tissue injury may be an accumulated overload injury and may develop secondarily to other lameness. The PT-PL tissue is most plantar in location, is thin, may be most vulnerable to injury from abnormal strain, and may be the first tissue in progression to be injured. Conformational abnormalities may predispose the horse to such injuries. The cause of such soft tissue injury in mature nonracehorses is unknown, and although swelling can develop with relatively mild lameness, more often lameness is moderate to severe.

Clinical examination reveals localized soft tissue swelling, often with heat and pain on palpation, with or without lameness. Previous application of liniments or blisters or pin firing may create sore skin and considerable soft tissue swelling. Ultrasonographic findings depend on the duration of the injury. Acute lesions have an accumulation of anechoic fluid subcutaneously; in more chronic injuries,

swelling is from subcutaneous echogenic material (see [Figures 78-8 to 78-10](#)). The SDFT, DDFT, and LPL should be inspected carefully, but they are frequently normal.

Management depends on the degree of lameness, the stage of training, the race or competition schedule, and the owner's or trainer's wishes. Blistering is used widely, but we question its value. Although not supported by scientific evidence, thermocautery (pin firing) appears to be an effective management tool, perhaps because it enforces rest. However, prolonged rest is rarely necessary in racehorses, and many horses can be managed by local injection of corticosteroids (triamcinolone acetate, 9 mg) without substantial interruption of training. More than one treatment may be required if the swelling and lameness do not resolve. A lame horse must be rested to prevent injury to deeper structures. In nonracehorses with moderate-to-severe lameness, lameness may take several weeks to resolve. If the swelling becomes firm, fibrous, and pain free but lameness recurs, further investigation is warranted, because other causes of tarsal pain often develop in STB and TB racehorses with curb.

Infection can occur from direct trauma with skin penetration, previous injection, or severe topical counterirritation. If infection is suspected, cytological examination and culture are indicated. If a hematoma resulting from trauma is large or recurrent or if the curb is infected, establishing drainage is often necessary. A distal incision is made to provide drainage, and fibrin and debris are removed. Care must be taken to avoid penetration of the tarsal sheath when creating the incision. A drain is inserted if necessary, and the hock is bandaged. Culture usually reveals *Staphylococcus* species, and appropriate antimicrobial and NSAID therapy is instituted. Horses are rested for 2 to 3 weeks to allow the tissues to heal, even though lameness from PT-PL tissue injury was not present before infection developed. Prognosis in horses with infection of PT-PL tissues is excellent but is far worse in those with infection of the SDFT, DDFT, or tarsal sheath.

Superficial Digital Flexor Tendonitis

A common finding in horses with curb is SDF tendonitis. Sickle-hocked conformation may predispose the horse to tendonitis, which can occur alone but rarely is seen without concomitant inflammation of the PT-PL tissues. Pathogenesis likely involves progressive or accumulated overload injury of first the thin, fragile PT-PL tissues and later the SDFT.

Previous PT-PL tissue injury appears to predispose to subsequent SDF tendonitis if the training level is increased quickly. PT-PL injury may simply be an early stage of a progressive lesion that eventually involves the SDFT or LPL. Progressive injury occurs frequently if horses with PT-PL tissue injury are treated with cryotherapy, internal blisters, or corticosteroids, and training intensity is accelerated before mature fibrous tissue can form. In horses with PT-PL tissue injury and SDF tendonitis, lameness varies, but it is much more likely to be observed than in horses with only PT-PL tissue injury. Lameness may be acute in onset and often is seen at fast speeds, but it can be seen in some horses at a trot in hand. SDF tendonitis occurs commonly in young STB racehorses but usually at a later stage of training than PT-PL tissue injury. Ultrasonographic examination reveals enlargement of the CSA of the SDFT, with a

variable change in echogenicity and fiber pattern, depending on the severity of the injury (see [Figure 78-11](#)). Often, subcutaneous edema or fibrosis occurs, depending on the chronicity of the injury.

In horses with SDF tendonitis, rest is an important part of management. Lesions usually are localized to the plantar aspect of the tarsus; those extending farther distally are associated with more severe lameness, and horses have a poorer prognosis. Horses with localized lesions have a fair prognosis, although the prognosis is worse in trotters than in pacers. Horses with mild acute SDF tendonitis, with enlargement of the tendon without fiber tearing, should be rested for 3 to 4 weeks. Without rest, progressive fiber damage may occur, resulting in prolonged recovery. Horses with more severe injuries may require up to 4 months of stall rest and controlled walking exercise.

In some STB racehorses actively racing, SDF tendonitis can be managed symptomatically, without giving rest, if the lesion is well localized and mild. Rest is always the best option but one often met with resistance from trainers. Mild lameness may be observed at speed or while the horse is trotting in hand, but severe lameness should not be evident. Ultrasonographic examination often reveals PT-PL tissue injury with enlargement of the SDFT, but core lesions are not present. In most horses local therapy using cold water hosing and poultice application, NSAID therapy, and subcutaneous injection of a corticosteroid preparation is successful. Subcutaneous injection of methylprednisolone acetate (200 mg) and Sarapin (25 mL) medial, plantar, and lateral to the SDFT is often done by practitioners with apparent success. Care is taken not to inject corticosteroids directly into the substance of the SDFT and LPL. Horses are given 10 to 14 days of jogging and light training before racing again. Nonracehorses with localized lesions usually respond well to rest for up to 3 months and have a favorable prognosis. Intralesional injections of fresh bone marrow, platelet-rich plasma, cultured stem cells, or other preparations may help healing and improve long-term prognosis, but we currently have no experience with intralesional therapy in this location.

Horses with severe SDF tendonitis have severe mushy swelling. If not given rest, these horses develop progressive tearing of the SDFT distal to the hock in the metatarsal region and lose support of the hock. Long-term rest (9 to 12 months) is recommended, but prognosis for return to previous race class is poor and in trotters, grave.

Deep Digital Flexor Tendonitis

DDF tendonitis is a rare cause of curb. Horses with curb resulting from DDF tendonitis are usually acutely lame and have substantial swelling. Mixed injury with DDF tendonitis accompanying SDF tendonitis and LP desmitis occurs, but it is unusual. Horses with DDF tendonitis have concomitant PT-PL tissue inflammation and effusion of the tarsal sheath (tenosynovitis). The DDFT simply can be enlarged compared with the contralateral limb or can have anechoic or hypoechoic core lesions. During ultrasonographic examination, the DDFT should be evaluated carefully from the midline and plantaromedial aspects. Lameness often is pronounced, and rest is recommended for a minimum of 4 to 6 months, but prognosis is guarded because lameness can recur. Serial ultrasonographic

examination, corrective shoeing, and controlled exercise are given.

Long Plantar Desmitis

LPL injury usually causes acute lameness, but chronic soft tissue swelling and progressive lameness can occur. Soft tissue swelling often is pronounced. Although LP desmitis can occur in racehorses, this form of curb appears to be equally common in other types of horses, such as Western performance horses. In one of the Editor's experience (SJD) LP desmitis is rare in sports horses in Europe. LP desmitis can be well localized or diffuse. Cross-sectional measurements of the LPL are critical, because desmitis often manifests as ligament enlargement rather than overt fiber tearing. Subtle thickening of the LPL may cause high-speed lameness, and evaluation of the CSA may be the only method to identify early lesions in these horses. Lesions can occur at any level within zones 1A and 1B, and injury may involve the insertion of the LPL on the MtIV (see [Figure 78-12](#)).

Conservative management is best for horses with LP desmitis, because lameness and swelling often are pronounced. Owners and trainers of nonracehorses are often open to a conservative approach involving ample rest (3 months) to rehabilitate horses with curb properly. Intervening with therapy to enforce rest is not necessary. Controlled return to exercise is straightforward in this type of horse, because walking and trotting under saddle can be given easily. Graded exercise programs are not administered as easily or desired in STB racehorses compared with nonracehorse sports horses. Lunging and walking and trotting under saddle are usually not practical, although riding trotters is popular among trainers originally from Europe. Walking and light jogging in a jog cart are the best methods for graded exercise in a STB racehorse. We do not recommend turnout exercise in any horse with soft tissue injury, because we feel strongly that this prolongs recovery and may lead to reinjury, but we realize our recommendations may not be followed. Cryotherapy, topical counterirritants, subcutaneous injections, and thermocautery are less likely to influence inflammation and healing of the LPL than more superficial causes of curb, but these treatments are sometimes requested. As experience is gained with intralesional therapy for management of soft tissue injuries in horses, it will undoubtedly be applied to injuries in the plantar aspect of the tarsus.

Curb can result from LP desmitis at its insertion on the MtIV. These horses do not have extensive swelling but focal thickening just proximal to the MtIV. Mild soft tissue swelling must be differentiated from a prominent but normal MtIV seen in yearlings with sickle-hocked conformation. Horses with curb resulting from distally located LP desmitis show lameness and mild, focal swelling and are managed with rest.

Mixed Soft Tissue Injuries

Ultrasonographic examination of curb nearly always identifies PT-PL tissue inflammation and in many horses an abnormality of the SDFT, DDFT, or the LPL. Occasionally, however, simultaneous injury of the SDFT and LPL occurs in addition to PT-PL tissue inflammation. This is most common in nonracehorse sports horses, in which lameness and swelling are severe. Long-term rest is recommended, but prognosis is guarded.

Chapter 79

Bursae and Other Soft Tissue Swellings

Sue J. Dyson

A bursa is a flattened, closed sac interposed between structures subject to friction or at points of unusual pressure, such as bony prominences and tendons. Bursae are lined with a cellular membrane resembling synovium and are classified according to position (subcutaneous, subligamentous, submuscular, and subtendonous) and according to the method of formation (congenital or acquired).

Acquired bursae develop because of pressure and friction over bony prominences. Tearing of the subcutaneous tissues results in accumulation of transudative fluid, which becomes encapsulated by fibrous tissue. In chronic injuries fibrous bands may develop within the capsule.

SUPRASPINOUS BURSA

The supraspinous bursa overlies the summits of the dorsal spinous process of the second to fifth thoracic vertebrae, under the funicular part of the nuchal ligament. Inflammation of the supraspinous bursa and surrounding soft tissues, so-called *fistulous withers*, is usually infectious in origin and may be a sequela to trauma. *Streptococcus* and *Staphylococcus* species, *Brucella abortus*, and *Onchocerca cervicalis* have been considered important causative agents.¹⁻³

Clinical signs of supraspinous bursitis are generalized soft tissue swelling, heat and pain, and often draining tract(s). Osteitis or osteomyelitis of the dorsal spinous processes of the cranial thoracic vertebrae may be concurrent. Care must be taken not to misinterpret the normal granular radiopaque appearance of normal, incompletely ossified summits of the dorsal spinous processes.⁴ Diagnostic ultrasonography and radiology are useful for determining the extent of the infection, for identifying a foreign body, and for evaluating signs of osteitis or osteomyelitis.

Treatment is by aggressive surgical debridement of all infected tissue and establishment of adequate drainage, taking care not to penetrate the dorsoscapular ligament. Several surgical procedures may be required to resolve the infection successfully.¹⁻³

INTERTUBERCULAR (BICIPITAL) BURSA

The intertubercular (bicipital) bursa is discussed in Chapter 40.

HYGROMA

Hygroma is discussed in Chapters 38 and 67.

NAVICULAR BURSA

The navicular bursa is discussed in Chapters 24 and 30.

TROCHANTERIC BURSA

The Editors have no clinical experience of trochanteric bursitis. This condition is discussed further in Chapter 47.

CALCANEAL BURSA

The calcaneal or intertendonous bursa lies between the tendons of the gastrocnemius and the superficial digital flexor muscles, proximal to the hock, and extends distally on the plantar aspect of the calcaneus to the distal aspect of the hock (Figure 79-1). In most horses a communication exists between the calcaneal bursa and the gastrocnemius bursa. There is communication between the calcaneal bursa and the subcutaneous bursa in 37% of horses.

Injuries of the calcaneal bursa are not common and are usually the result of trauma. However, mild distention of the calcaneal bursa often is seen with gastrocnemius tenosynovitis (see page 803). Mild distention also may be seen unilaterally or bilaterally, as an incidental finding unassociated with lameness.⁵ Primary inflammation of the bursa results in acute-onset lameness associated with distention of the bursa. Hemorrhage into the bursa also may occur. Conservative management by rest, with or without injection of short-acting corticosteroids, usually results in resolution of lameness, although enlargement of the bursa may persist.

More commonly, infection of the bursa is caused by a penetrating injury or is secondary to infectious osteitis of the calcaneus^{6,7} (see Chapter 44).

Chronic distention of the calcaneal bursa also has been seen with well-circumscribed osteolytic lesions on the

tuber calcanei, which were thought to represent enthesopathy at the insertion of the gastrocnemius tendon.⁸

Further investigation should include diagnostic ultrasonography, radiography of the calcaneus, and synoviocentesis. Radiographic examination should include a flexed skyline image of the calcaneus.⁹ The internal structure of the bursa may be evaluated endoscopically,¹⁰ but some underlying bony lesions may not be visible if the insertion of gastrocnemius is intact.⁸ Endoscopy has been used diagnostically and therapeutically in horses with infectious osteitis, or bursitis, and in those with osteolytic lesions.

Horses with primary infection of the calcaneal bursa should be treated by debridement and lavage of the bursa and broad-spectrum antimicrobial therapy. Horses with infectious and noninfectious lesions of the calcaneus have been managed conservatively and surgically, with rather disappointing results.⁶⁻⁸ Repeated surgeries are often required, and a substantial number of treated horses have persistent lameness.

SUBCUTANEOUS ABSCESS OVER THE TUBER CALCANEI

Puncture wounds in the region of the hock frequently result in penetration of the calcaneal bursa and infectious bursitis. Less commonly a subcutaneous abscess develops associated with firm, painful swelling on the plantar aspect of the hock and lameness. The extent of soft tissue swelling may make accurate palpation difficult, and ultrasonography is essential to determine whether or not the calcaneal bursa is involved. Radiographic examination of the calcaneus is also required. Treatment is by radical surgical debridement. The long-term functional outcome is usually satisfactory, although there is usually residual swelling (capped hock).

GASTROCNEMIUS BURSA

The subgastrocnemius bursa usually communicates with the calcaneal or intertendonous bursa. Mild distention may be present, unassociated with lameness. Primary injuries of the gastrocnemius bursa are rare. The bursa may be distended in association with gastrocnemius tendonitis, resulting in a capped hock appearance (see page 804). Occasionally, infection may occur because of a puncture wound or extension of infection from the calcaneal bursa.

CAPPED HOCK

A capped hock appearance may be caused by distention of the gastrocnemius bursa, distention of the subcutaneous bursa, or development of an acquired bursa over the tuber calcanei (see Figure 6-28). An acquired bursa develops because of repetitive trauma, such as the horse kicking the stable walls or leaning backward on its hindlimbs when traveling. Capped hock usually has no associated lameness. Protection of the hocks with hock boots may help to prevent deterioration.

CUNEAN BURSA

The cunean bursa lies underneath the cunean tendon on the medial aspect of the hock. Inadvertently penetrating

the bursa is easy if one is inexperienced in injecting the centrodistal joint. Although the potential for primary bursitis exists, neither of the Editors of this text recognizes primary bursitis as a cause of lameness in racehorses or other sports horses. Gabel recognized a syndrome, "cunean tendonitis and bursitis–distal tarsitis syndrome of harness racehorses," but appreciated that horses showed substantially better improvement in gait after intraarticular analgesia of the distal hock joints than after infiltration of the cunean bursa alone.¹¹ Nonetheless, a component of periarthicular soft tissue pain may occur in Standardbred trotters and pacers with distal hock joint pain, and treatment of the cunean bursa with corticosteroids frequently is used as part of management. Cunean tenectomy is practiced by some, but it has largely fallen from favor. Subcutaneous injection of corticosteroids and Sarapin over the proximal aspect of the second metatarsal bone may yield better results than medication of the cunean bursa.⁵

CAPPED ELBOW

A capped elbow is an acquired bursa that develops over the olecranon of the ulna. The bursa results from repeated trauma from the heel of the shoe on the ipsilateral forelimb when the horse is lying down. The condition generally is not associated with lameness and is merely a cosmetic blemish. The use of a sausage boot around the pastern prevents trauma from the shoe, and usually the swelling diminishes substantially and rapidly in size. Horses with chronic injuries have been treated by injection of corticosteroids, orgotein, or dysprosium-165, with disappointing results, or surgically, with better cosmetic results.¹²

ACQUIRED BURSA ON THE DORSAL ASPECT OF A HIND FETLOCK

Firm swelling on the dorsal aspect of the hind fetlocks of horses that jump fixed fences is common. These lesions are false bursae that overlie the extensor tendon and are usually of no consequence, except cosmetically. However, a puncture wound may result in infection, causing enlargement of the bursa and surrounding soft tissue swelling, localized heat, and pain on palpation.⁵ In contrast to infection in a joint or tendon sheath, lameness is usually only mild to moderate. Ultrasonography is useful to better identify the causes of the soft tissue swelling, and diagnosis is confirmed by synoviocentesis and identification of many nucleated cells. Surgical treatment is required, and the prognosis is good.

FALSE THOROUGHPIN

A *thoroughpin* is the colloquial name for distention of the tarsal sheath, but more commonly the term is misused to describe a variety of swellings that may develop in the distal aspect of the crus cranial to the gastrocnemius tendon. These conditions are otherwise called *false thoroughpins* and should be differentiated from distention of the tarsal sheath, tarsocrural joint capsule (see Chapter 44), or calcaneal bursa (see page 799). A false thoroughpin occurs laterally more commonly than medially and may develop unilaterally or bilaterally. A false thoroughpin

Fig. 79-2 • Plantar view of a right hock. A false thoroughpin (arrow). The swelling in this horse was acute in onset, but it was unassociated with lameness. The horse was maintained in full work, and despite this the swelling reduced in size. Ultrasonographic evaluation revealed a unilocular fluid-filled cavity.

varies in size from small to large. In contrast to distention of the tarsal sheath or the plantar outpouching of the tarsocrural joint capsule, these swellings cannot be balloted from laterally to medially and do not extend distal to the hock (Figure 79-2). They may be sudden or insidious in onset and may or may not be associated with lameness.

The causes vary and are poorly understood. False thoroughpins are usually solitary, fluid-filled sacs (Figure 79-3), unilocular or multilocular, with a wall of variable thickness, with or without large echogenic fibrous bands traversing them (Figure 79-4). They may develop secondary to local hemorrhage or because of herniation of the tarsal sheath or the calcaneal or gastrocnemius bursae.¹³⁻¹⁵

Diagnostic ultrasonography is useful to identify the nature and extent of the swelling (see Figure 79-4). Unlike the tarsal sheath, no tendon is within the cavity. Positive-contrast radiography can be used to demonstrate whether any communication exists between adjacent structures (see Figure 79-3).

A false thoroughpin may be an incidental clinical finding unassociated with lameness. The condition is seen commonly in horses with a base-narrow hindlimb conformation.⁵ Other causes should be excluded before one concludes that a false thoroughpin is the cause of lameness. Even if the swelling is acute in onset, in the absence of lameness I have maintained horses in work with no deleterious effects. Sometimes such swellings spontaneously reduce in size, but some swelling is likely to persist.

Long-term lameness associated with a false thoroughpin has been seen in a number of horses with chronic hindlimb lameness that has not responded to conservative management. Surgical excision of large multiloculated

Fig. 79-3 • Dorsolateral-plantaromedial oblique radiographic image of a hock. A positive-contrast radiographic study of false thoroughpin. This fluid-filled cavity did not communicate with the tarsal sheath.

cystlike lesions has resolved lameness successfully in some horses,⁵ although cosmetic results may be disappointing.

Spherical Masses Close to the Fetlock

Small, focal, hard, nonpainful spherical swellings are sometimes seen on the palmarolateral (plantarolateral) or

palmaromedial (plantaromedial) aspect of the fetlock adjacent to the digital flexor tendon sheath (DFTS). These do not generally cause lameness. Ultrasonographic examination reveals a fluid-filled mass. Lameness associated with herniation of the DFTS is discussed in Chapter 74, page 776.

Chapter 80

Other Soft Tissue Injuries

Sue J. Dyson

RUPTURE OF THE FIBULARIS (PERONEUS) TERTIUS

Anatomy

The fibularis (peroneus) tertius is an entirely tendinous muscle that lies between the long digital extensor and the cranialis tibialis muscles, which cover the craniolateral aspect of the tibia. The fibularis tertius originates from the extensor fossa of the femur. Distally the fibularis tertius divides into branches that enfold the tendon of insertion of the tibialis cranialis and insert on the dorsoproximal aspect of the third metatarsal bone, the calcaneus, and the third and fourth tarsal bones. The tendon is an important part of the reciprocal apparatus of the hindlimb, which coordinates flexion of the stifle and hock.

The fibularis tertius is the most echogenic structure on the craniolateral aspect of the crus and is identified readily by ultrasonography as a well-demarcated hyperechogenic structure relative to the surrounding muscles (Figure 80-1).

History and Clinical Signs

Rupture of the fibularis tertius invariably is caused by trauma resulting in hyperextension of the limb; for example, a horse trying to jump out of a stable and getting one hindlimb caught on the top of the stable door. This usually results in rupture of the tendon in the middle of the crus but occasionally farther distally. Alternatively, rupture may be caused by a laceration on the dorsal aspect of the tarsus, resulting in transection of the tendon. Occasionally, partial tearing of the tendon occurs, usually at the level of the tarsocrural joint, with prominent swelling. Occasionally the reciprocal apparatus is partially but not totally disrupted. Avulsion injuries of the origin of the tendon rarely occur in young foals. Injury close to the origin is unusual in mature horses, occurring in two of 25 adult horses with fibularis tertius injury.¹

The clinical signs are pathognomonic, because rupture of this tendon allows the hock to extend while the stifle is flexed. When standing at rest, the horse may appear

Fig. 80-1 • Transverse ultrasonographic images of the craniolateral aspect of the midcrus of 7-year-old horse with left hindlimb lameness of 2 months' duration. The fibularis tertius is the most echogenic structure in the center of the image of the right (*R*) hindlimb (*solid arrow*). Compare this with the image of the left (*L*) hindlimb, in which the fibularis tertius is markedly hypoechoic (*open arrow*). Note also that the overlying muscle is increased in echogenicity compared with the right hindlimb.

Fig. 80-2 • A horse with rupture of the fibularis tertius. The hock can be extended while the stifle is flexed. Note also the characteristic dimple in the contour of the caudodistal aspect of the crus. Clinical signs developed after the horse had attempted to jump out of its stable and had got hung up on the door. The horse made a complete recovery.

clinically normal, although with acute injury careful palpation may reveal some muscle swelling on the cranio-lateral aspect of the crus or farther distally. When the horse walks, it should be viewed carefully from behind and from the side. The hock may extend more than usual. The tendons of gastrocnemius and the superficial digital flexor muscles may appear unusually flaccid, and a dimple is seen on the caudal aspect of the crus about one handbreadth proximal to the tuber calcanei. At the trot the horse appears severely lame, with apparent delayed protraction of the limb because of overextension of the hock.

If the limb is picked up and pulled backward, the hock can be extended gradually and “clunks” into complete extension while the stifle remains flexed. A characteristic dimple appears in the contour of the caudal distal aspect of the crus (Figure 80-2). If rupture is only partial, or if lameness is chronic and some repair has taken place, clinical signs may be less severe and the diagnosis less obvious.

Presumably, strain of this tendon can occur, resulting in lameness, but I have no experience of this, and to my knowledge this condition has not been documented.

Diagnosis

The diagnosis of rupture of the fibularis tertius is based on the pathognomonic clinical signs. The site of rupture can be identified with ultrasonography (see Figure 80-1). The normally echogenic structure is not clearly identifiable and may be replaced by a region that is hypoechoic relative to the surrounding muscles. In horses with chronic injuries the surrounding muscles may become hypertrophied. Usually no associated radiological abnormalities are apparent in adult horses, although avulsion fracture of the origin has been described in foals.

Treatment

Confinement to box rest for 3 months, followed by a slow resumption of work, usually results in total resolution of clinical signs. Most horses are able to return to full athletic function without recurrence of clinical signs; however, injury may recur if work is resumed prematurely. Healing

should be monitored ultrasonographically. Fifteen of 21 horses (71%) returned to full athletic function, with a mean convalescent period of 41 weeks.¹ Performance horses were less likely to return to their former activity than pleasure horses. Site and cause of injury (laceration or trauma) did not influence the outcome, but the presence of other injuries adversely influenced the prognosis. Delayed recognition of the clinical signs and failure to confine the horse may result in a chronic lesion, which fails to heal satisfactorily. However, compensatory hypertrophy and/or fibrosis of surrounding muscles may permit functional recovery.^{1,2}

COMMON CALCANEAL TENDONITIS

The common calcaneal tendon consists of components from the superficial digital flexor and gastrocnemius tendons and from the biceps femoris, soleus, semimembranosus, and semitendinosus muscles. Contributions from the last two muscles are called the *axial* and *medial tarsal tendons*. So-called “common calcaneal tendonitis” has resulted from a kick in the hock region.³ Unfortunately, the horse was not examined with ultrasonography until 5 months after injury, at which time soft tissue swelling was marked. Ultrasonographic examination revealed that the superficial digital flexor and gastrocnemius tendons appeared normal, but the axial and medial tarsal tendons were enlarged. The horse made a complete functional recovery.

GASTROCNEMIUS TENDONITIS

Tendonitis of the gastrocnemius is a relatively unusual cause of hindlimb lameness in the horse.⁴⁻⁶ Disruption of the gastrocnemius in neonatal foals is discussed separately.

Anatomy

The gastrocnemius muscle arises from two heads that terminate in the midcrus in a common tendon. Proximally the tendon lies caudal to the superficial digital flexor tendon (SDFT); farther distally the tendon lies laterally and is ultimately cranial, inserting on the tuber calcanei. The SDFT and gastrocnemius tendons are separated by a bursa, the calcaneal or intertendonous bursa, that extends to the midtarsal region. A small bursa, the subgastrocnemius bursa, also lies cranial to the insertion of the gastrocnemius tendon on the tuber calcanei. A communication usually exists between these bursae. The intertendonous bursa also communicates with a subcutaneous bursa in approximately 37% of horses.

The tendon of the gastrocnemius may still contain some muscular tissue as far distally as the level at which it lies lateral to the SDFT. This results in hypoechoic regions within the tendon.

Gastrocnemius tendonitis usually occurs distally, distal to the musculotendonous junction. Rarely, damage occurs at the musculotendonous junction.⁷ Occasionally, injuries occur at the origin of the gastrocnemius on the distal caudal aspect of the femur.⁸

History and Clinical Signs

Lameness may be acute or gradual in onset and varies from mild to severe. Distention of the subgastrocnemius and

Fig. 80-3 • Medial view of the left hock of a 7-year-old Thoroughbred with acute-onset lameness associated with gastrocnemius tendonitis. Note the capped-hock appearance (*black arrowhead*) and the distention of the calcaneal bursa (*white arrowhead*).

calcaneal bursae frequently is associated with gastrocnemius tendonitis, and the horse often develops a capped-hock appearance because of distention of the subcutaneous bursa (Figure 80-3). However, these swellings can occur without lameness or detectable pathological conditions of the gastrocnemius or SDFT (see page 799). Mild enlargement of the gastrocnemius tendon may occur, but this can be difficult to appreciate. Eliciting pain by palpation usually is not possible. Occasionally there are no palpable abnormalities.

Severe lameness is characterized by a reduced height of arc of foot flight, shortened cranial phase of the stride, and a tendency to hop off the caudal phase of the stride. Horses with less severe lameness have no specific gait characteristics. Lameness often is accentuated by proximal or distal limb flexion. Two of four horses with injury to the origin of the gastrocnemius muscle had an unusual gait characterized by internal rotation of the affected limb (outward movement of the calcaneus).⁸ One of the Editors (MWR) has seen a horse with gastrocnemius tendonitis exhibit a similar, unusual gait in the affected limb. Care should be taken to not overinterpret this clinical finding in sound horses, because bilaterally symmetrical internal rotation of the hindlimbs can be a normal finding. A severe injury at the origin of the gastrocnemius muscle may result in an abnormal posture, with the hock of the affected limb lower than that of the contralateral limb.

Diagnosis

Lameness associated with gastrocnemius tendonitis is improved substantially by perineural analgesia of the tibial nerve, possibly because of local diffusion of the local

Fig. 80-4 • Transverse ultrasonographic image of the caudal distal aspect of the crus of a 6-year-old mare with left hindlimb lameness that was alleviated by perineural analgesia of the tibial nerve. Medial is to the left. The gastrocnemius tendon is enlarged, its caudal lateral aspect is poorly defined (*arrowheads*), and there is a large hypoechoic region consistent with gastrocnemius tendonitis.

anesthetic solution. Diagnosis is confirmed by ultrasonographic examination. Comparison with the contralateral limb is useful. Lesions usually occur distal to the musculotendonous junction but do not involve the insertion on the tuber calcanei.

The tendon usually is damaged in the distal aspect of the crus, where it lies cranial to the SDFT. Ultrasonographic abnormalities include enlargement of the tendon, poor definition of the margins, and focal or diffuse hypoechoic or anechoic regions (Figure 80-4). Usually no detectable radiological abnormalities are apparent. In young Thoroughbred racehorses there may be increased radiopharmaceutical uptake (IRU) in the tuber calcanei, which should prompt investigation of the gastrocnemius tendon as a potential cause of lameness. Ultrasonographic assessment of the gastrocnemius tendon is also warranted if lameness is abolished by perineural analgesia of the tibial and fibular nerves, but no potential cause of lameness is identified in the hock or proximal metatarsal regions.

Injury at the origin of the gastrocnemius muscle on the caudal aspect of the femur may be associated with IRU and, if chronic, radiological evidence of proliferative new bone formation.⁸

Treatment and Prognosis

Conservative treatment with box rest and controlled exercise for up to 12 months generally has resulted in progressive improvement in lameness associated with gastrocnemius tendonitis and improvement in the ultrasonographic appearance of the tendon. Horses with mild lesions have been able to return to full athletic function without recurrent lameness, but those with more severe lesions have a more guarded prognosis.^{5,6} Overall 14 of 25 horses managed conservatively have returned to full athletic function.⁹ However two horses with moderate or severe lesions that

failed to respond to conservative management subsequently returned to full athletic function after intralesional treatment with β -aminopropionitrile fumarate.⁹ Three of four horses with injury of the origin of the gastrocnemius returned to athletic use, but recurrent injury occurred in the fourth horse.⁸

DISRUPTION OF THE GASTROCNEMIUS IN NEONATAL FOALS

Disruption of gastrocnemius in neonatal foals is an unusual cause of hindlimb lameness or an inability to stand.^{10,11} The condition has often been associated with dystocia. Partial or complete rupture usually occurs at the proximal musculotendinous junction, resulting in soft tissue swelling over the caudodistal aspect of the femur. Injury is usually unilateral, although it is occasionally bilateral. Diagnosis is based on the stance of the foal and detection of soft tissue swelling and is confirmed by ultrasonography. Foals able to bear weight are treated by stall rest alone; a sleeve cast or splints are applied to those that are unable to load the limb. Complications include severe hemorrhage associated with the injury, leading to cardiovascular compromise (three of 28 foals, 11%); concurrent disease (17 of 28, 61%); abscess formation at the site of rupture (four of 28, 14%); and cast sores (seven of 18, 39%).¹¹ Historically the prognosis was considered guarded,¹⁰ but in a recent report 23 (82%) of 28 foals survived to discharge from the hospital, and 13 (81%) of 16 horses that reached 2 years of age trained or raced.¹¹

SUBLUXATION AND LUXATION OF THE SUPERFICIAL DIGITAL FLEXOR TENDON FROM THE TUBER CALCANEI

Lateral (see Figure 6-29), or less commonly medial, luxation or subluxation of the SDFT from the point of the hock may occur along with damage to or rupture of the retinacular bands that insert medially and laterally on the tuber calcanei. Although usually a unilateral injury, the condition can occur bilaterally.

Lateral displacement of the SDFT occasionally occurs secondarily to hyperextension of the hind fetlock associated with progressive breakdown of the suspensory apparatus in older horses (see Figure 72-24 and page 760).

Anatomy

The SDFT lies caudally in the distal aspect of the crus and broadens to form a cap over the tuber calcanei. At this level, broad, thick retinacular bands extend medially and laterally to insert on the tuber calcanei. The calcaneal bursa is interposed between the SDFT and the tendon of gastrocnemius.

History and Clinical Signs

Partial or complete disruption of one of the retinacular bands that attach the SDFT to the tuber calcanei can result in subluxation or, more commonly, luxation of the SDFT laterally or medially. Occasionally the SDFT tendon splits sagittally, with the tendon luxating both medially and laterally. Lameness is usually sudden in onset and severe, although occasionally mild lameness precedes this, associated with soft tissue swelling in the region of the

point of the hock. Frequently no history of trauma is apparent, and the injury often occurs as the horse is being worked. The horse may suddenly stop and may become extremely distressed, especially if the tendon repeatedly moves on and off the tuber calcanei. The horse may kick out repeatedly with the limb. The tendon may return to its normal position when the horse bears weight. Soft tissue swelling rapidly ensues, resulting in a capped hock appearance, making accurate palpation difficult. If the horse is kicking repeatedly when moving, one may conclude wrongly that the soft tissue swelling developed as the result of trauma caused by kicking.

With subluxation of the SDFT, the tendon is usually positioned normally at rest. Careful observation of the tendon as the horse moves may reveal instability. With luxation it may be possible to see that the SDFT has been displaced laterally or, less commonly, medially. If the tendon remains luxated, then the horse tends to be less agitated, although obviously in pain in the acute stage. Careful palpation may reveal instability of the tendon or its displacement to an abnormal position.

In horses in which lateral displacement occurs secondary to hyperextension of the fetlock, the condition may be insidious in onset and slowly progressive and unassociated with acute lameness.

Diagnosis

Ultrasonographic examination is helpful if the tendon is displaced by confirming its abnormal position, but such examination can add to confusion if the tendon is in the normal position when the horse stands still. It may be possible to identify a partial tear in the medial, or less commonly the lateral, retinacular band. The calcaneal bursa may be distended, and if the condition is chronic there may be synovial proliferation. Occasionally there is a longitudinal split in the SDFT, which adversely affects prognosis.

Treatment

In the acute stage pain relief is essential, and tranquilization may be necessary to calm the horse. If the SDFT is unstable and is moving constantly on and off the tuber calcanei, management in the acute and chronic phases may be difficult. If the tendon is permanently dislocated laterally or medially, the distress usually resolves rapidly. Antiinflammatory drugs are best avoided, because the surrounding soft tissue swelling helps stabilize the tendon. If the tendon has luxated laterally, prolonged rest (6 months) usually results in resolution of pain, although a mechanical lameness may persist. This limits the horse's function for dressage, but these horses may be able to race or show jump at a high level. The prognosis associated with medial luxation is more guarded and tends to be associated with a greater degree of mechanical lameness.

If the SDFT is unstable initially, the tendon may with time and progressive further disruption of the attaching retinacular bands become more stable in a luxated position. Peritendinous injection of a sclerosing agent, P2G (Martindale Pharmaceuticals, Romford, Essex, England), has been helpful in stabilizing the luxated tendon in a limited number of horses.⁹ Surgical transection of a partially torn retinacular band has helped in chronic subluxation.⁹ Attempts at surgical stabilization of the SDFT in its normal position often have been disappointing, although

successful results have been reported.^{12,13} Surgical stabilization is worth considering only if the horse is temperamentally suited to a full-limb cast. Prognosis is influenced by the ease of reconstruction of the torn retinaculum, which depends on the site of the tear (close to the tendon, close to the bone, or midway) and its age.

BICEPS BRACHII TENDONITIS

Biceps brachii tendonitis is discussed in Chapter 40.

Chapter 81

Tendon Lacerations

Sue J. Dyson and Alicia L. Bertone

Tendon lacerations are serious injuries in horses because of the loss of the biomechanical function of the tendon, the slow return of tendon strength, the immediate strenuous loading demanded by a horse, and the complications of scarring. Nonetheless, early diagnosis, wound management, limb support, and long-term surgical and medical management have resulted in a good prognosis for most horses with extensor tendon lacerations and a fair prognosis for most of those with flexor tendon lacerations.¹² The extensor (dorsal) aspect of the limb is often damaged by

INFECTION OF THE COMMON DIGITAL EXTENSOR TENDON

Infection of the common digital extensor tendon and its sheath is usually the result of a puncture wound with or without deposition of a foreign body such as a blackthorn. It results in swelling, heat, pain, and lameness (see also page 789). Successful management was described by complete resection of the infected tendon.¹⁴

wire or a sharp object over which the horse has jumped. The flexor (palmar or plantar) aspect of the limb may be traumatized by circumferential wire injuries, landing on a sharp object, or being struck. The latter may be self-inflicted or from another horse.

DIAGNOSIS

Gross Appearance of the Wound

Any laceration over the dorsal or palmar/plantar surface of the limb distal to the stifle or elbow, especially across the dorsal aspect of the tarsus, distal dorsal aspect of the tarsus, dorsal metatarsal region, distal aspect of the radius, dorsal metacarpal region, and dorsal fetlock region may involve a tendon (Figure 81-1). Extensor tendons and the superficial digital flexor tendon (SDFT) are positioned directly under the skin; therefore minor-appearing wounds can transect these tendons completely. Direct visual inspection may reveal transected tendon fibers protruding from the

Fig. 81-1 • Diagram illustrating common sites of tendon injury. **A**, Lateral forelimb. **B**, Medial forelimb. **C**, Lateral hindlimb. **D**, Medial hindlimb. 1, Dorsal tarsus; 2, dorsal metatarsal region; 3, distal radius; 4, dorsal metacarpal region; 5, dorsal fetlock region; 6, palmar metacarpal region; ECRM, extensor carpi radialis muscle; CDE, common digital extensor muscle; LDE, lateral digital extensor muscle; DDFM, deep digital flexor muscle; SDFM, superficial digital flexor muscle; SL, suspensory ligament. (Adapted from Bertone AL: Tendon laceration in tendon and ligament injuries. Part II, *Vet Clin North Am Equine Pract* 11:293, 1995.)

wound. However, injuries sustained at the gallop may result in a skin wound removed from the site of tendon damage because of the movement of the skin during exercise. The position of the wound relative to synovial structures should be evaluated with care because concurrent synovial contamination or infection reduces the prognosis and necessitates specific emergency treatment.

Evaluation of Gait

Each tendon serves a biomechanical function. Complete severance of a tendon results in a posture or gait change, which may be pathognomonic for disruption of the tendon integrity.

Extensor Tendons

Transection of an extensor tendon below the carpus produces a reduced ability to extend the digit, which is detected as an exaggerated, rapid (uncontrolled) dorsal flip of the hoof at the walk. This subtle change is easiest to detect if the lateral and common (or long) digital extensor tendons are transected completely. Intermittently the horse knuckles at the fetlock joint and places the digit on the dorsal surface of the pastern and fetlock joint. The gait abnormality is more obvious in a hindlimb and with lacerations in close proximity to the fetlock. Remaining peritendinous fascial attachments provide some support in horses with more proximal injuries. Horses with extensor tendon lacerations bear weight fully in a normal posture, unless other aspects of the wound create lameness and pain.

Transection of extensor tendons proximal to the carpus and at, or just proximal to, the tarsus also commonly occurs. Proximal to the carpus, transection of the extensor carpi radialis and common digital extensor tendons is most frequent. Flexion of the carpus may cause pain. The tendon sheath is often involved.

Proximal or dorsal to the tarsus, transection of the long digital extensor, cranialis tibialis, and fibularis (peroneus) tertius tendons is most frequent. If the fibularis tertius is disrupted, the hock can be extended while the stifle is flexed, indicating loss of the reciprocal apparatus. The gastrocnemius tendon develops a characteristic wrinkle in this extended position (see Figure 80-2 and page 802). The degree of gait abnormality may be mild. Transection of all the extensor tendons over the tarsus still allows full weight bearing with the foot flat on the ground. A greater tarsal extension during the swing phase of the stride and intermittent knuckling of the digit can be detected.

Digital Flexor Tendons

Transection of the digital flexor tendons below the carpus or tarsus produces pain on weight bearing and therefore lameness and gait abnormality. Transection of the SDFT is most common because it has the most superficial position of the two digital flexor tendons. The suspensory ligament (SL) is deep to the deep digital flexor tendon (DDFT) and is therefore least commonly injured with lacerations. A horse with complete transection of the SDFT may stand normally, or it may bear weight on the toe of the hoof to minimize movement of the tendon ends with fetlock joint extension. Complete transection of one branch of the SDFT in the pastern may not alter the stance during full load bearing. Administration of phenylbutazone for pain may eliminate lameness, and a gait abnormality may become

hard to detect. The DDFT and SL support the fetlock joint together with the SDFT. Therefore slight hyperextension of the fetlock because of disruption of the SDFT may be difficult to detect unless the contralateral limb is picked up. The greater the number of structures transected, the less support to the fetlock and other distal joints and the greater the likelihood of vessel and nerve transection. Elevation of the toe is pathognomonic for transection of the DDFT.

Digital Palpation of the Wound

Digital palpation is a simple and direct way to determine the extent of damage to structures below the skin. Integrity of the tendons is readily determined by feel. Partial tears can be distinguished from complete tears, and this affects treatment (see [Partial Tendon Lacerations](#) section). The tendon ends are often palpable beneath the skin proximal and distal to the wound, but they may be removed from the wound if the injury was sustained while the horse was galloping. The muscular attachment to the proximal end pulls the proximal tendon end farther from the wound. The wound should be clipped around the edges and cleansed thoroughly with a dilute antiseptic solution such as chlorhexidine before exploration. Gross debris can be debrided manually from the wound. Sterile gloves should be worn for the digital exploration after the wound is clean. Digital palpation may reveal involvement of a tendon sheath or joint capsule; however, small tears of these synovial structures may not be palpable. Sterile preparation of the skin and injection of a balanced electrolyte solution into the synovial structure in question at a site distant from the wound may demonstrate communication if solution exits the wound. Synovial fluid also can be obtained and submitted for cytological evaluation. Hemorrhage or inflammation is usually present in the synovial fluid if a sheath has been penetrated. Mild inflammatory changes can be seen in synovial structures adjacent to tendon injuries, even if no actual communication with the wound occurs.

Ultrasonographic Evaluation

Ultrasonographic evaluation of the tendons can quantitate the degree of tendon damage, particularly in horses with partial tears. Ultrasonographic examination is not necessary for diagnosing complete tears and therefore is performed rarely. Ultrasonography may also be technically difficult in the region of a skin wound because air in the wound impairs transmission of ultrasound waves. A partial laceration of the SDFT may be associated with the development of longitudinal splits extending proximodistally as a result of altered shear stresses. Complete transection of a branch of the SDFT in the pastern region may result in a shift of position of the branch proximal to the transection toward the side of the intact branch.

Ultrasonographic evaluation can be useful during the healing phases of horses with partial or complete tendon lacerations.³ The amount of repair tissue should increase early in repair and then decrease as the tissue matures and gains strength. In digital flexor tendons, about 6 weeks are required for the tendon to gain the strength to support 450 kg, and the strength of the repair tissue is largely because of an increase in tissue mass. The repair tissue cross-sectional area is greater than the original tendon area,

but the strength of that tissue per unit area is reduced.⁴ The quality of the repair tissue can be monitored with ultrasonography. Ultrasonographic examinations should show progressively increased homogeneity of echogenicity, reduction in the hypoechoic areas of damaged tendon or early immature repair tissue, and appearance of parallel arrangements of fibers.

EMERGENCY MANAGEMENT

Treatment of Shock

Trauma is often severe in horses with lacerated tendons, particularly digital flexor tendons. Some horses may be trapped for hours in wire or entangled in equipment. Blood loss may be extensive if major arteries to the distal limbs have been transected. The loss of the function of a limb is painful and stressful. Initial management of these horses can be lifesaving. If possible, the horse should be caught and brought into a warm, clean area for examination and further treatment. If the horse has severe tachycardia (>100 beats/min) with pale mucous membranes and is reluctant to move, initial treatment should be performed on site. If the wound is still bleeding, a clean pressure bandage should be applied to stop the bleeding and provide some support to the limb. If the function of the limb is impaired mechanically, a splint should be applied over the bandage to minimize further damage with movement. Use of tranquilizers and sedatives should be kept to a minimum until the degree of blood loss and shock can be assessed and treated. Most sedatives are peripheral vasodilators and may produce substantial hypotension in a hypovolemic horse. Some horses may be in stress-induced shock from pain, with extreme catecholamine release. The effect of tranquilizers may be unpredictable and potentially can worsen the bleeding. Securing the horse in a familiar, warm, clean environment and stabilizing the injured limb may resolve the stress-related shock and allow assessment of hemorrhagic shock by evaluating peripheral pulse strength and quality, heart rate, and mucous membrane color. If hemorrhagic shock is severe, the most important treatment is intravenous fluid volume replacement, which can be in the form of high-volume isotonic fluids (20 to 60 L minimum per 450 kg of horse) or hypertonic saline (9% NaCl; 1 L per 450 kg of horse), followed by isotonic fluid replacement. Hypertonic fluid therapy can be effective for rapid expansion of the vascular space in hemorrhagic shock, but hypertonic solutions dehydrate the interstitium and induce a profound renal diuresis. Therefore it is critical that isotonic fluid therapy begins within 30 minutes to 1 hour after hypertonic fluid administration. Hypertonic fluid therapy is practical because of the convenience of the small volumes necessary and works well if the horse is referred or transported to a facility that has access for fluid administration.

Transportation

For transportation the injured limb should be placed toward the back of a trailer. The horse's weight shifts to the front of a trailer during braking, which is often less controlled than acceleration. The horse's head should not be tied tightly, so the head and neck can be used for balance. The limb should be supported with a padded pressure bandage and a splint for transport.

MEDICAL MANAGEMENT

All horses with tendon lacerations need medical therapy, whether surgery to reapproximate tendon ends is elected or not. If tendon laceration, partial or complete, is diagnosed, a more thorough aseptic preparation of the wound should be performed. These procedures require sedation, restraint, and local or regional analgesia.

Wound Cleansing and Debridement

The hair should be clipped circumferentially from above the wound (to the estimated top of the bandage) and the entire limb distal to the wound. Drainage of serum and exudate from the wound is often voluminous, and removal of the hair makes subsequent cleaning of the limb easier and more thorough, thereby minimizing bacterial growth and contamination. A 10-minute scrub of the wound with an antiseptic solution should be performed. If bone and tendon are exposed, care must be taken to minimize trauma to these tissues. A minor sterile instrument pack may be helpful in trimming heavily contaminated tissues and lacerated tendon ends, as well as for removing hair and debris from deep in the wound. Lacerated tendons should be trimmed at the edges to remove traumatized tissue that is expected to become necrotic. Debridement of tendon ends should be most conservative in horses with digital flexor tendon lacerations, for which apposition of tendon ends with suture is recommended.

Systemic and Local Medications

Tetanus toxoid should be administered to any horse with a tendon laceration, and tetanus antitoxin should be given if no vaccination history exists. Because all wounds are contaminated at injury and compound wounds have extensive soft tissue injury, broad-spectrum antimicrobial drugs should be administered systemically for a minimum of 3 days. Metronidazole should be considered in horses with grossly contaminated distal extremity wounds. The duration of antimicrobial therapy may be longer in horses with heavily contaminated wounds, wounds healing by second intention, infected wounds, wounds involving a tendon sheath, or wounds with delayed treatment (>24 hours). Wound lavage should be copious, usually with a minimum of 5 L of a balanced electrolyte solution.

SURGICAL TREATMENT

Surgery in the form of wound closure is performed in most horses with open wounds involving tendons. Primary closure is preferred, if possible, to provide the best success of obtaining primary wound healing, minimal scar formation, and the fewest complications associated with the transected tendon. However, wounds that are heavily contaminated, older than 24 hours, or heavily traumatized should have a delayed closure (1- to 3-day delay) performed to reduce the contamination and necrotic debris before closure. The decision to close a wound older than 24 hours must be made based on the condition of the wound and surrounding structures. Wounds in horses that have been managed appropriately from the time of injury until surgery can be closed at any time, if tissue loss is minimal and infection is not present.

Extensor Tendons

Transected extensor tendons heal well without primary suturing of the tendon, even if a large gap has formed between the tendon ends. Serial ultrasonographic evaluations show fibrosis occurring between the tendon ends that eventually becomes more organized and regains the linear arrangement of collagen along the pattern of the original tendon. This fibrous tissue seems to provide a mechanical link between the tendon ends because extensor function of the digit returns in most horses. In our experience, a palpable thinning of the new tendon and an enlargement at the old tendon ends usually remains, even after 1 year.

Horses with lacerated extensor tendons have a good prognosis, with 73% of injured horses returning to athletic soundness and 18% to pasture soundness.² In that study, 62% of the affected horses were treated with a three-layer cotton bandage, 23% with a splint and bandage, and 10% with fiberglass casts.

It is important that the horse is confined to box rest for at least 6 weeks so that lameness does not ensue. With lameness the hoof may be positioned on the toe, and the force of the digital flexor tendons maintains this position, particularly without the counterforce of the extensor tendon. Chronic flexor pull may result in permanent flexural deformity and lameness. If flexor dominance is noted, a splint or cast should be applied (see Chapter 86).

In our experience, the best cosmetic outcome, as well as chances of achieving primary wound closure, occurs with using a fiberglass cast for 3 to 6 weeks. The cast provides the most immobility to the limb and the lacerated tendon ends. Early fibrosis matures more quickly, without disruption of the early granulation tissue.

Digital Flexor Tendons

Horses with complete laceration of one or more digital flexor tendons are best treated with tendon suturing, wound closure, and postoperative immobilization for about 6 weeks. Digital flexor tendons support the weight of the horse on loading. Thus healing and return to full strength is a slow process, one that does not return to normal for at least 6 months. In studies investigating methods of tendon repair, immobilization of the limb in a cast without suturing produced a significantly weaker repair that resulted in the clinical sequela of a hyperextended fetlock joint.^{4,5} The amount of scar tissue filling the tendon gap was significantly less in this group compared with the sutured groups and was the reason for the reduced strength. Therefore suturing of digital flexor tendon injuries is recommended. Monofilament suture (nylon or polyglyconate) produced the greatest strength of repair compared with carbon fiber suture when placed in a double-locking loop pattern (nylon) or three-loop pulley pattern (polyglyconate) for apposition of tendon ends or for spanning tendon gaps.⁴⁻⁶ The limb should be cast for at least 6 weeks, with the fetlock joint in mild flexion, by building a heel support with casting tape or plaster to provide a level weight-bearing surface with the ground.

Repairs of flexor tendon lacerations above the hock (i.e., gastrocnemius tendon, DDFT, or SDFT) should follow the same principles, but the prognosis is decreased because of the greater difficulty in maintaining a full-limb cast, larger size of the tendons at this location, and greater biomechanical stresses to support the hock with weight bearing.

Partial Tendon Lacerations

Horses with partially transected tendons can be treated successfully without suturing but with wound closure and limb immobilization. Partial transection of digital flexor tendons usually involves the SDFT only or the axial margin (medial or lateral) of the SDFT and DDFT. If the limb is immobilized, the remaining fibers of tendon provide the stability for the torn tendon ends to remain in apposition and provide the strength to prevent further tendon tearing during healing. Anecdotally, if more than 75% of the SDFT is lacerated, tendon suturing may provide a reduced gap and faster healing and improve the repair. If the SDFT is completely transected along with a partial laceration of the DDFT, the SDFT should be treated with suturing as previously described and the DDFT left unsutured.

Lacerations in Tendon Sheaths

If a laceration enters a tendon sheath, then therapy is altered to include aggressive lavage of the sheath and wound, intrathecal administration of antibiotics, close monitoring of sheath fluid cytological condition, longer use of systemic antibiotics, and limb immobilization. If tissue loss is minimal, wounds entering tendon sheaths should be closed primarily. Primary closure and fiberglass cast application offer the best chance of early healing and minimize the potential for the complications of ascending infection, chronic drainage and fistulae formation, and fibrosis.

CONVALESCENT THERAPY

Shoeing

After removal of a cast or splint for horses with extensor tendon lacerations, a gradual return to full weight bearing is recommended. Shoeing recommendations are simple and include trimming or shoeing level, without toe extensions that may catch and produce knuckling. For horses with digital flexor tendon lacerations, an elevated and extended heel shoe can be applied and the heel lowered sequentially over the next 6 weeks to a flat position. For severe lacerations involving the DDFT, SDFT, or SL, an extended heel shoe may always be required for additional flexor support.⁷

Graduated Exercise

Horses with extensor tendon injuries have not been evaluated as closely during the healing process to assess tissue maturation and return of strength as those with digital flexor tendon injuries. Because the function of the extensor tendon is to extend the digit and not endure a load on weight bearing, return to full strength may occur sooner than for digital flexor tendons. Horses should remain in a box stall or a confined area during the wound healing phases and early fibroblastic repair phases of tendon healing (3 to 6 weeks). After this time, handwalking and controlled exercise such as swimming can begin to strengthen the tendon and improve gliding function. After 10 to 12 weeks of controlled exercise, and if no signs of knuckling or flexor dominance are present, gradual return to athletic use can begin.

Horses with digital flexor tendon lacerations require a more gradual convalescent period. After the first 6 weeks of immobilization, the next 6 weeks should be spent in

confinement and regaining a normal foot posture and full weight bearing. Heel support shoes are applied during this time. After 12 weeks, handwalking can begin and gradually increase in frequency and duration over the next 3 to 6 weeks. Controlled exercise with walking, lunging, swimming, or ponying (leading from another horse) is preferred to turnout. Turnout can be given after the horse is sound at the walk and trot and ultrasonographic examination demonstrates extensive fibrosis and mature scar tissue. Heavy athletic use should not begin until 8 to 12 months after the injury.

PROGNOSIS

Successful outcome (soundness) occurs in about 75% of horses with extensor tendon lacerations and up to 54% of horses with digital flexor tendon lacerations.^{1,2,8} The

prognosis for horses with partial disruption of the SDFT, DDFT, or both is better than for those with complete lacerations.⁸ Long-term failures are attributable to continued pain from extensive adhesions, joint pain, other injury at the time of laceration, tendon sheath adhesions, tendon contracture, palmar (plantar) annular ligament constriction, reinjury, and failure of the repair to regain adequate strength to support the joint, leading to breakdown. Reinjury to a damaged tendon may occur during healing, but such a tendon can heal successfully, although convalescence is prolonged. In general the prognosis is better for pleasure riding horses than for sports horses, but especially with injuries involving the digital flexor tendons of a hindlimb, complete function may be restored. An association exists between lacerations of either or both the long and lateral digital extensor tendons in the proximal part of the metatarsal region and the subsequent development of stringhalt several months later.⁹

Chapter 82

Soft Tissue Injuries of the Pastern

Virginia B. Reef and Ronald L. Genovese

Injuries to the digital flexor tendons and ligaments in the pastern are a common cause of lameness in horses.¹⁻⁶ Injuries to the collateral ligaments or the palmar or plantar ligaments of the proximal interphalangeal joint are a less frequent cause of lameness.^{1,7-9} Swelling, heat, and sensitivity of the affected tendon or ligament to palpation often accompany lameness. Ultrasonographic evaluation of the pastern is indicated when local swelling, heat, and sensitivity are detected, or when effusion occurs in the digital flexor tendon sheath (DFTS).¹⁰ The cause of the swelling can be determined by ultrasonography, and the severity of the injury can be characterized. The clinician should keep in mind that peripheral longitudinal splits in the digital flexor tendons within the DFTS are difficult to detect and can be missed ultrasonographically.¹⁰ If injury occurs to the superficial or deep digital flexor tendons (SDFT, DDFT) in the metacarpal or metatarsal region, ultrasonographic examination should include an evaluation of these structures in the pastern. Lameness associated with soft tissue injuries of the pastern also can occur without localized soft tissue swelling, and ultrasonographic examination is indicated if pain is localized to the region using diagnostic analgesia and no radiological abnormality is detected, or enthesioid new bone is seen. The clinician should bear in mind that intraarticular analgesia of the metacarpophalangeal or metatarsophalangeal joints, the proximal interphalangeal joint, and the DFTS is not necessarily specific and may influence closely related structures such as the distal sesamoid ligaments and the palmar ligaments of the proximal interphalangeal joint. It also may be important

to use diagnostic analgesia to determine whether the injury causing soft tissue swelling in the pastern region is the source of the lameness. Nuclear scintigraphy may help to determine whether enthesioid new bone is active, and magnetic resonance imaging (MRI) has the potential to provide additional information. This chapter focuses on lesions diagnosed using ultrasonography, but the absence of detectable ultrasonographic abnormalities does not preclude soft tissue pathology causing pain.

ANATOMY

Most of the soft tissue structures in the pastern are on the palmar or plantar aspects and are similar in the forelimbs and hindlimbs. The following describes the forelimb but applies equally to the hindlimb. The SDFT forms a thin ring around the DDFT at the ergot and in the proximal-most portion of the pastern and then bifurcates into medial and lateral branches. The origin of the branches has a teardrop shape. The cross-sectional area (CSA) of each SDFT branch gradually enlarges as the branch extends distally along the palmarolateral and palmaromedial aspects of the pastern, until the branches insert on the distal aspect of the proximal phalanx and on the proximal aspect of the middle phalanx. The DDFT lies immediately dorsal to the SDFT and extends along the midline to its insertion on the distal phalanx.^{1-6,11-15} The DDFT has a bilobed shape in the pastern and is surrounded by the DFTS. The oblique (middle) sesamoid ligaments (OSLs) originate from the base of the lateral and medial proximal sesamoid bones (PSBs) as two large, round to oval branches. These branches become smaller in CSA as they extend distally. The branches join in the proximal to mid aspect of the proximal phalanx and insert as a broad band on the palmar aspect of the middle of the proximal phalanx. The straight sesamoid ligament (SSL) also has its origin at the base of the PSBs and the palmar ligament and extends distally in the midline, palmar to the OSL, to insert on the scutum medium of the middle phalanx.^{1-6,11-13,16} The SSL lies dorsal to the DDFT and has an hourglass shape, larger proximally and distally, and narrowest in the middle.

The DFTS surrounds the SDFT and DDFT throughout the proximal aspect of the proximal phalanx to the bifurcation of the SDFT.^{1-6,11-15,17} The entire length of the DDFT is included in the DFTS, except for a small area in the distal palmar aspect of the pastern, just proximal to the bulbs of the heel. The dorsal aspect of the DFTS extends farther distally than its palmar aspect. The proximal digital annular ligament is adhered closely to the palmar aspect of the SDFT in the proximal aspect of the pastern.^{1,3-5,18} The distal digital annular ligament forms a sling over the distal part of the DDFT. These two structures are thin in normal horses.

The abaxial and axial palmar ligaments of the proximal interphalangeal joint originate in pairs from the medial and lateral aspects, respectively, of the middle of the proximal phalanx and dorsal to the SDFT branches. They insert on the scutum medium abaxial to the branches of the SDFT (abaxial palmar/plantar ligament) and between the SSL and the branches of the SDFT (axial palmar/plantar ligament). These are large, round to oval ligaments that extend in a diagonal direction from the origin to the insertion. The collateral ligaments of the proximal interphalangeal joint originate from a small eminence on the lateral and medial aspects of the proximal phalanx, distal to the origin of the palmar ligaments, and arc across the joint to insert on a small eminence on the lateral and medial aspects, respectively, of the proximal aspect of the middle phalanx.^{1,3,7,11} The proximal interphalangeal joint has a closely adhered joint capsule.

The common digital extensor tendon is located on the dorsal aspect of the pastern.¹ The extensor branches of the suspensory ligament (SL) join the common digital extensor tendon in the distal part of the proximal phalanx. The main insertion of the common digital extensor tendon is on the extensor process of the distal phalanx, but there are also areas of insertion onto the proximal and middle phalanges. A bursa is present between the tendon and the proximal interphalangeal joint.

ULTRASONOGRAPHIC ANATOMY

The pastern has been divided into five zones: three zones for the proximal phalanx and two zones for the shorter middle phalanx^{1-6,12-15} (see Chapter 16).

Superficial Digital Flexor Tendon

In the proximal aspect of the pastern (zone P1A), the SDFT is imaged from the palmar aspect and is homogeneously echogenic and has a thin, half-moon shape in the transverse plane.^{1-6,12-14} In longitudinal images the SDFT has a parallel fiber pattern and a triangular shape along the midline in zone P1A because its thickness decreases distally. In normal horses, distinguishing the proximal digital annular ligament from the DFTS and the palmar border of the SDFT is difficult. The proximal digital annular ligament can be identified if thickened by following it medially and laterally to its attachment to the proximal aspect of the proximal phalanx. The body of the SDFT ranges in thickness (palmar to dorsal) from 2 to 6 mm in P1A to 1 to 4 mm over the middle of the proximal phalanx.³ The teardrop-shaped branches in the proximal to mid pastern region (at the junction of zones P1A and P1B) are imaged from the palmaromedial and palmarolateral aspects and

are followed individually to triangular-shaped insertions. The SDFT branches are similarly homogeneously echogenic, with a parallel fiber pattern throughout. The branches of the SDFT range in thickness from 4 to 7 mm in the proximal pastern to 7 to 12 mm distally.¹⁵ The CSA of the two SDFT branches ranges from 0.3 to 0.4 cm² in the distal portion of zone P1A where the branch begins, increases to 0.4 to 0.6 cm² in zone P1B, and further enlarges to 0.6 to 0.8 cm² near the insertion.

Deep Digital Flexor Tendon

The DDFT has an oval to bilobed appearance in the pastern and is imaged on the palmar midline of the pastern until the DDFT is lost from view distally.^{1-6,12-15} The two lobes are symmetrical. The fibers of the DDFT extend obliquely from a deeper to a more superficial position in the more distal portion of the pastern and are separated from the SSL by an anechogenic space. The dorsopalmar thickness and lateral to medial width of the DDFT decrease in the mid pastern and increase again in the distal aspect of the pastern. The DDFT measures 5 to 10 mm (palmar to dorsal) in the proximal aspect of the pastern, slightly less in the mid pastern, and 7 to 12 mm in the distal aspect of the pastern. The width of the DDFT in a lateral-to-medial direction ranges from 18 to 33 mm in the proximal aspect of the pastern, decreasing to 15 to 23 mm in the mid pastern, and increasing in the distal aspect of the pastern to 23 to 32 mm.³ Along the dorsal aspect of the DDFT in the mid pastern region is a synovial fold of the DFTS that is imaged readily, surrounded by a small amount of anechogenic synovial fluid. In the distal pastern region, the palmar aspect of the DDFT adheres to the synovial membrane of the DFTS.

Oblique Sesamoidean Ligaments

Injury to the OSLs is often missed ultrasonographically because the origin and proximal to midportion of each OSL (where the majority of the injuries are) are not imaged from the palmaromedial and palmarolateral aspects of the limb. The origin of the medial or lateral OSL is best found by placing the ultrasound transducer over the base of the medial or lateral PSB and scanning distally over the bone to its base, angling the transducer proximally to image the origin of the respective OSL.^{1-6,12,13} Alternatively, the origin of an OSL can be found by following the SL branches distally over the respective PSBs to the base. Immediately distal to the base of the PSB is the origin of an OSL, best located initially in its transverse section as a large, round to oval structure. The OSLs merge in the distal part of zone P1A into a broad, rectangular band dorsal to the DDFT. The OSLs then insert on the palmar or plantar aspect of the proximal phalanx in zone P1B. An OSL is the most difficult tendon or ligament to follow longitudinally to its insertion because the ligament extends diagonally from its origin to its insertion in two different planes. Following the medial or lateral OSL from its origin to the main body of OSL requires a transducer angle of about 45 degrees from the base of the PSBs to the palmar midline of the proximal phalanx. Properly aligning the transducer and eliminating off-normal incidence artifact is difficult. The OSLs may appear less echogenic because of an oblique orientation. The OSLs are thickest in the medial to lateral direction proximally. Each OSL measures 12 to 20 mm (lateral to

medial) in the proximal aspect of P1A, decreasing to 9 to 17 mm just before their convergence, and 0 to 9 mm (one side only) at their insertion. The palmar to dorsal thickness of the OSLs is 5 to 12 mm in P1A, decreasing to 2 to 6 mm just proximal to the convergence, and decreasing again to 0 to 3 mm at the insertion. The mean CSA of an OSL determined with MRI is reported to be 0.86 cm² in the proximal third, 0.56 cm² in the middle third, and 0.40 cm² in the distal third.¹⁹ However, there may be size differences between the medial and lateral OSLs.²⁰

Straight Sesamoidean Ligament

The origin of the SSL is found by angling the transducer in a proximal and dorsal direction from the proximal-most aspect of the pastern, just underneath the ergot, to image the ligament and the base of the PSBs. The SSL becomes a more oval-shaped structure and is palmar to the OSLs in zone P1B. The SSL remains dorsal to the DDFT as it inserts on the scutum medium.

The dorsal-to-palmar thickness of the SSL gradually increases as the medial to lateral width decreases. The SSL measures 5 to 9 mm (palmar to dorsal) proximally, increasing slightly over the distal aspect of the proximal phalanx to 6 to 12 mm, and increasing again to 8 to 14 mm at the scutum medium. The medial-to-lateral thickness of the SSL ranges from 17 to 30 mm in zone P1A, decreases to 10 to 15 mm, and then widens over the scutum medium to 45 to 65 mm.³ The SSL is echogenic with normal parallel fiber alignment throughout, except at the insertion. A central symmetric hypoechoic area is commonly imaged in clinically normal horses at the insertion of the SSL.¹⁶ Care must be taken to be sure that lesions are not created at the insertion of the SSL because of the difficulty in aligning the transducer perpendicular to the ligamentous fibers owing to the horse's heel. Comparison of this area with the contralateral normal limb should aid in determining whether a suspected lesion is real.

Cruciate Sesamoidean Ligaments

The cruciate sesamoidean ligaments are imaged only in the proximal-most portion of the pastern and measure 2 to 4 mm in a palmar to dorsal direction.³

Collateral Ligaments

The collateral ligaments of the proximal interphalangeal joint are easiest to examine by imaging in both longitudinal and transverse planes. The collateral ligaments of the proximal interphalangeal joint are homogeneously echogenic structures, with a parallel fiber pattern at the origin on the distal aspect of the proximal phalanx to the insertion on the proximal half of the middle phalanx.^{1,2}

Proximal Interphalangeal Joint

The proximal interphalangeal joint is easiest to image initially in the longitudinal plane by identifying the joint space, and then a transverse evaluation of the joint can be made.⁷ Fluid normally is not imaged in the proximal interphalangeal joint.

Palmar/Plantar Ligaments of the Proximal Interphalangeal Joint

The palmar ligaments of the proximal interphalangeal joint can be imaged from the origin on the middle of the

proximal phalanx to the insertion on the proximal palmar aspect of the middle phalanx. These ligaments are paired on the medial and lateral aspects of the pastern and are located by placing the transducer dorsal to the branch of the SDFT. The more abaxial branch originates first and is easier to follow than the more axial branch. Each branch has a round to oval shape, is homogeneously echogenic with a parallel fiber pattern, and must be followed individually from origin to insertion.

Digital Nerves

The digital nerves are located dorsal to the lateral and medial aspects of the SDFT, adjacent to the lateral or medial palmar digital arteries.¹ The nerves are found most easily by identifying the digital vein and artery, looking immediately adjacent (palmar) to the digital vein and the adjacent SDFT. The nerves are tiny, homogeneously echogenic circular structures. The normal thickness of the palmar or plantar digital nerves is 2 to 3 mm, with a CSA of 0.5 to 1 mm².¹

TENDON AND LIGAMENT INJURIES

In the fore pastern, the SDFT is the most frequently injured tendon or ligament in all performance horses.^{1-6,21} The OSLs are the second most commonly injured structures in the fore pastern, followed by injuries to the DDFT and SSL.¹⁻⁶ In the hind pastern, injuries to the DDFT are most common, with a low incidence of injuries to the other tendinous and ligamentous structures.¹⁻⁵ Injuries to the DDFT are accompanied most often by tenosynovitis of the DFTS.¹⁻⁶ Injuries to the collateral ligaments of the proximal interphalangeal joint occur infrequently and are more common in the forelimb.^{1,3,7} Injuries to the palmar/plantar ligaments of the proximal interphalangeal joint are also uncommon and occur in forelimbs (most common) and hindlimbs. The tendinous and ligamentous structures in the pastern have little covering, and thus they are vulnerable to injury with puncture wounds and lacerations. Ultrasonographic evaluation of the pastern region in a horse with an acute laceration or puncture wound to the pastern should be performed aseptically and is an integral part of the evaluation of these soft tissue structures to determine whether injury occurred and the severity of the injury.

Superficial Digital Flexor Tendonitis

Injuries to the branches of the SDFT are more common in the forelimb.^{1-6,21,22} Injury in the pastern may occur in isolation, without an injury to the SDFT in the metacarpal or metatarsal region, or may be an extension of a more proximal tendon injury. Extension of the SDFT injury into the proximal pastern region, and less frequently into the mid and distal pastern, is more common in the forelimb. Abnormal conformation such as a long pastern, an under-run heel, or an axially displaced heel may predispose to injury of an SDFT branch.

Lameness usually occurs at the onset of injury, is more common with SDFT injuries in the pastern than with those in the metacarpal or metatarsal region, and may persist longer, lasting for 1 to 4 weeks. Longitudinal swelling that extends in a proximal-to-distal direction along the lateral or medial aspect of the pastern throughout its length is often characteristic.^{1,2,21} Focal heat and sensitivity usually

Fig. 82-1 • Ultrasonographic images of the right front medial branch of the superficial digital flexor tendon obtained in the proximal part of zone P1C in a horse with a recent injury. The anechoic to hypoechoic core lesion is apparent within the branch (arrows) in the transverse (left) and longitudinal (right) views. Fiber disruption and short linear fibers are imaged within the lesion in the longitudinal view, consistent with a recent injury and early healing. The horse was 1 of 5 degrees lame, with focal swelling, heat, and sensitivity to palpation.

accompany this swelling. However, in horses with acute injuries, no localizing clinical signs may be apparent, but lameness is alleviated by palmar (abaxial sesamoid) nerve blocks. Generally, swelling develops within 3 to 4 days. Ultrasonographic examination in the absence of swelling may result in false-negative results. Subluxation of the proximal interphalangeal joint can occur in horses with severe injury to or complete rupture of the SDFT in the pastern. Dropping of the fetlock joint with weight bearing can occur in horses with severe SDFT injury.

Core injuries are the most common detected by ultrasonography (Figure 82-1), followed by diffuse injury to the affected branch.^{1,2} Complete ruptures or near complete ruptures of the branches do occur, but they are less frequent. These injuries can be unilateral or bilateral and uniaxial or biaxial, although uniaxial injuries are most common. The frequency of injury to the medial or lateral SDFT branch varies with the type of racing or sporting activity.^{21,22} Peritendinous soft tissue swelling is common. Avulsion fracture of the insertion of the SDFT branch occurs infrequently. Ultrasonographic evaluation of the more proximal aspect of the SDFT in the metacarpal or metatarsal region is indicated to determine whether the injury is an extension of a more proximal injury (see Chapter 69) (Figure 82-2). Ultrasonographic evaluation of the contralateral fore or hind pastern is recommended because bilateral disease may be present, more frequently in the forelimb. Radiological examination of the pastern is indicated for all horses with subluxation of the proximal interphalangeal joint, avulsion fractures at the insertion of the SDFT branch, or a ruptured SDFT branch.

Treatment for horses with acute superficial digital flexor tendonitis in the pastern is similar to that in the metacarpal or metatarsal region.^{1,2} Horses with SDFT injuries in the pastern may have a poorer prognosis for returning to racing than those with injuries in the metacarpal region, with a more frequent recurrence of injury.^{1,2,22} Extension of the injury from the pastern to the metacarpal area may also occur, resulting in a shortened racing career.²¹ However,

Fig. 82-2 • Ultrasonographic images of the left superficial digital flexor tendon (SDFT) in the metacarpal region (A) and pastern (B) obtained from a horse with an acute severe injury to that tendon. This horse was lame at the walk, with substantial swelling of the SDFT in the metacarpal and pastern regions and heat and sensitivity of the tendon on palpation. The metacarpophalangeal joint dropped on weight bearing. **A**, The SDFT is enlarged (arrows) and contains a large central anechoic lesion completely lacking in tendon fibers. The SDFT was severely injured in the metacarpal region from 7 to 32 cm distal to the accessory carpal bone. The SDFT in zone 3C is surrounded by a thickened hypoechogenic digital flexor tendon sheath (DFTS). The transverse image is on the left, and the longitudinal image is on the right. **B**, The SDFT in zone P1A is markedly enlarged (arrows) with a central anechoic lesion that extended distally to the insertion of the lateral branch. The surrounding DFTS and peritendinous tissues are greatly thickened and hypoechogenic, and the distinction between the palmar margin of the SDFT and the peritendinous structures is difficult to discern. The lateral branch of the SDFT has nearly complete fiber disruption that extends to its insertion. The lateral side of the proximal pastern is the right image, and the medial side of the pastern is the left image. The SDFT and the DFTS were so enlarged that they could not be imaged in their entirety in a single image. Therefore the two halves of the SDFT were displayed together in these transverse images.

successful return to performance does occur for horses with SDFT branch injuries. Rare horses are able to continue to compete with SDFT branch injuries, without a period of rest, but these are the exceptions rather than the rule. Healing of the SDFT occurs similarly to that in the metacarpal region, with an increase in the echogenicity of the lesion and the subsequent appearance of short, usually randomly aligned linear echoes. Rehabilitation of horses with injuries to the SDFT branch is similar to that described for proximally located tendonitis and is based on the injury severity (see Chapter 69). A minimum of 6 months in a

Fig. 82-3 • Ultrasonographic images of the left front lateral branch of the superficial digital flexor tendon obtained in zone P1B of a horse with a chronic healed core injury. The horse had sustained the original injury more than 5 years earlier, and after a long, controlled exercise program the horse had raced successfully several times a year, although some small areas of reinjury were detected periodically, necessitating short periods of downtime from race training. The original central core lesion is still visible in this branch as an echogenic central area, with a thin hypoechoic rim (arrow) in the transverse view (left) and longitudinal (right) views. In the longitudinal view, the central area of the tendon has a more random fiber pattern than the periphery (arrows).

controlled exercise program is needed for horses with mild SDFT branch injury, whereas 12 months or more are indicated for those with severe injury to the SDFT branch to maximize the horse's chance of returning to its previous level of competition. Ultrasonographic monitoring of tendon healing is an important part of the rehabilitation program. A central echogenic scar surrounded by a hypoechoic halo may be detected in the SDFT branch with a healed core lesion (Figure 82-3). Peritendonous echogenic tissue representing immature and maturing fibrous tissue often is imaged adjacent to the injured SDFT branch and can result in adhesions between the branch and the surrounding tendonous and peritendonous structures. New areas of fiber disruption often occur adjacent to the previously healed area or are associated with adhesions to the surrounding tendonous or peritendonous structures.

Deep Digital Flexor Tendonitis

Deep digital flexor tendonitis is discussed in Chapter 70.

Distal Sesamoidean Desmitis

Oblique Sesamoidean Desmitis

Desmitis of an OSL is the most common distal sesamoidean ligament injury and is seen in all types of performance horses.¹⁻⁶ Horses with a valgus or varus limb conformation or a long sloping pastern may be at increased risk for OSL injuries. Swelling in the pastern region in horses with OSL injuries is characteristic because this ligament runs diagonally across the proximal to mid pastern, and swelling of the pastern usually occurs in this direction. Many horses have a boxy appearance to the fetlock joint from swelling at the origin of an OSL. Most horses have local swelling, heat, and pain detected on palpation of the affected ligament and lameness in the affected leg. However, some lesions restricted to the origin of the ligament occur without palpable abnormalities. Chronic injuries may be associated with dorsal enlargement of the dorsal articular margins of

Fig. 82-4 • Ultrasonographic images of the origin of the left hind lateral oblique sesamoidean ligament (OSL) obtained in zone P1A. Most of the OSL is hypoechoic (arrow) in the transverse (left) and longitudinal (right) views (proximal is to the right). Substantial fiber disruption is visible in the longitudinal view, beginning at the base of the proximal sesamoid bone (arrow). There is no normal fiber pattern imaged at the origin of the lateral OSL. The more anechoic abaxial region represents a more recent injury, whereas the more echogenic area axially with a random fiber pattern represents a more chronic area of injury that is repairing. Some periligamentous echogenic soft tissue thickening surrounds the branch. The horse had a concurrent distal suspensory desmitis involving both suspensory branches that extended from 37 to 47 cm distal to the point of the hock. The horse was 2 of 5 degrees lame and had local heat, swelling, and mild sensitivity of the lateral OSL.

the proximal interphalangeal joint. Subluxation of the proximal interphalangeal joint can also occur in horses with either chronic injuries or complete rupture of the OSLs. This is characterized clinically by a dorsally convex profile of the pastern. Complete biaxial rupture of the OSLs is more common in Thoroughbreds and can have catastrophic implications. Injury to the medial OSL is more common than lateral OSL injury and is more common in the forelimb than in the hindlimb.³ Hindlimb OSL injuries are more common in nonracehorses. Horses with SL injury are also at increased risk of injuring the OSLs. Therefore ultrasonographic evaluation of the SL is recommended for all horses with oblique sesamoidean desmitis.

Discrete core lesions often are seen in both OSLs, although diffuse areas of fiber damage and splits also occur (Figure 82-4). Injuries to the insertion of an OSL are usually diffuse (Figure 82-5). Periligamentous soft tissue thickening is often seen. Comparison of the ultrasonographic findings in the affected limb with the contralateral limb is recommended to be sure that subtle or early injuries are not missed. The origin and insertion of the OSLs should be carefully evaluated for avulsion fractures.^{1,2} Avulsion fractures usually occur in association with fiber tearing in the distal sesamoidean ligaments and occur from the base of the PSBs (Figure 82-6) and the insertion on the proximal phalanx. Avulsion fractures remain visible for years after the original injury, long after the associated desmitis in the distal sesamoidean ligament has resolved. Radiographs of the fetlock (particularly the PSBs) and the pastern regions should be obtained in all horses with OSL desmitis, paying careful attention to the base of the PSBs. However, it is important to recognize that entheses new bone on the base of one or both of the PSBs or on the midpalmar aspect of the proximal phalanx can be seen as incidental radiological abnormalities, unassociated with lameness or active desmitis. Homogeneously radiodense mineralized bodies

Fig. 82-5 • Transverse (right) and longitudinal (left) ultrasonographic images of the right fore lateral oblique sesamoidean ligament (OSL) obtained where the two OSLs join. The lateral aspect of the transverse view is on the right side of the image. This horse had sustained an acute injury to the lateral OSL from the base of the lateral proximal sesamoid bone to its insertion. A large anechoic to hypoechoic core lesion (arrows) is visible. The horse was lame at the walk, with mild subluxation of the proximal interphalangeal joint and local swelling, heat, and sensitivity along the entire lateral OSL. DDFT, Deep digital flexor tendon; SSL, straight sesamoidean ligament; SDFT, superficial digital flexor tendon.

Fig. 82-6 • Transverse (left) and longitudinal (right; proximal to the right) ultrasonographic images of the medial oblique sesamoidean ligament (OSL) obtained in zone P1A of the left forelimb in a horse with chronic active desmitis of the OSL and a small basilar sesamoid fracture. The hyperechoic bony fragment (open arrow) is distracted away from the base of the proximal sesamoid bone (PSB) in the longitudinal view. Hyperechoic areas are visible in the transverse view (large arrows), and areas of amorphous and random fiber pattern are imaged in the longitudinal view, proximal and distal to the fracture fragment. There is cortical irregularity of the base of the PSB (small arrows) in the longitudinal image. The horse was 1 of 5 degrees lame, with thickening of the base of the lateral PSB but no heat or local sensitivity.

are also sometimes seen distal to the PSBs as incidental findings.

Since MRI has become used more frequently in the search for a diagnosis for horses with pain causing lameness localized to the fetlock or pastern region by diagnostic analgesia, the limitations of ultrasonography for injury diagnosis in the pastern have become more apparent.^{19,20,23} Injuries of the OSLs, SSL, and cruciate ligaments may be overlooked. Moreover, local analgesic techniques may be confusing. Pain associated with proximal lesions of these ligaments can be abolished by intraarticular analgesia of the fetlock or by intrathecal analgesia of the DFTs.²³ However, care should be taken in the interpretation of signal intensity alterations on magnetic resonance images of the OSLs because of the magic angle effect,²⁴ and the variable alignment of fibers in the proximal part of the

ligaments.²⁵ Lesions characterized by an increase in size of an OSL and increased signal intensity in T1- and T2-weighted images can be seen as incidental findings in association with other primary causes of lameness.²⁰ However, genuine primary lesions can be identified.^{19,23} Thirty-nine sports horses with pain localized to the fetlock region underwent MRI because conventional imaging techniques failed to yield a diagnosis.²³ Injury of one or more of the distal sesamoidean ligaments was identified as the primary cause of lameness in 21 (54%) horses.

Horses with acute injuries to the OSLs should be managed in the same way as those with other tendon and ligament injuries, with initial antiinflammatory therapy and exercise restriction.^{1,2} A controlled exercise program with incremental increases in the exercise level should be based on ultrasonographic monitoring. As the injury heals, the CSA of the ligament usually decreases, the echogenicity of the lesion increases, and linear echoes are imaged in the area of previous fiber tearing. A long recuperative period usually is indicated for horses with desmitis of an OSL to maximize the chance of return to athletic function.

Prognosis for horses with OSL injury is guarded to grave for returning successfully to racing and other competitive athletic activities and depends on the severity of the injury. Horses with coexisting suspensory desmitis, basilar fractures of the PSBs, or subchondral palmar third metacarpal or plantar third metatarsal bone disease have a poorer prognosis for return to athletic function. The incidence of recurrence of OSL injury is high. Prognosis is grave for athletic horses with subluxation of the proximal interphalangeal joint associated with distal sesamoidean desmitis.

Straight Sesamoidean Desmitis

Injuries to the SSL occur infrequently and may occur alone or with other soft tissue injuries.¹⁻⁶ These injuries usually are associated with lameness, but focal heat, swelling, and sensitivity are not always detected. Lameness is usually acute in onset and may be severe. Some horses, especially those with proximal lesions, never develop localizing soft tissue swelling, and diagnosis depends on localizing pain to the pastern region by diagnostic analgesia and subsequent ultrasonographic identification of a lesion. The ease with which the most proximal aspect of the ligament can be seen depends on the conformation of the horse and the position of the ergot. Ultrasonographic evaluation of the SSL is most difficult in horses with short pasterns and easiest in those with relatively long, upright pasterns.

Small splits or core lesions may be seen in the SSL.¹⁻⁶ Large areas of fiber disruption in the SSL are uncommon (Figure 82-7). Areas of periosteal proliferative change or avulsion fractures at the insertion of the SSL on the proximal aspect of the middle phalanx may be seen (Figure 82-8). Avulsion fractures of the origin of the SSL are less common than with OSL desmitis, but the base of the PSBs should be evaluated carefully.

Treatment for horses with SSL desmitis is similar to that recommended for horses with OSL desmitis.¹⁻⁶ Horses with mild injuries have returned successfully to racing, but the prognosis for horses with more severe lesions is guarded for any form of competitive athletic function because recurrent injury is common. Horses with multiple tendinous or ligamentous injuries in the pastern have a guarded to grave prognosis for returning to full athletic function.

Fig. 82-7 • Ultrasonographic images of the right hind pastern obtained in zone P1A from a horse with an acute injury to the straight sesamoidean ligament (SSL). The horse was lame at the walk, with swelling of the proximal palmarolateral aspect of the pastern and local heat and sensitivity. The large anechogenic lesion (arrows) in the plantar aspect of the SSL is visible in the transverse view (left), with complete fiber disruption in this region that is best imaged on the longitudinal view (right). The SSL is mildly enlarged along the midline in the dorsal to palmar direction. Note also the markedly thickened subcutaneous tissues.

Fig. 82-8 • Ultrasonographic images of the left fore straight sesamoidean ligament (SSL) obtained in zone P1C-P2A from a horse with an acute severe injury to the SSL and an avulsion of its insertion onto the scutum medium. The horse was lame at the walk, with subluxation of the proximal interphalangeal joint and substantial soft tissue swelling of the palmar pastern, with local heat and pain on palpation of the oblique sesamoidean ligament (OSL) and SSL. The hypoechoic lesion (small arrows) in the distal-most portion of the SSL and the hyperechoic fragment distracted away from the middle phalanx (large arrows) are visible in the transverse (right) and longitudinal (left) views. There is anechogenic effusion (open arrows) in the digital flexor tendon sheath. DDFT, Deep digital flexor tendon.

Cruciate Sesamoidean Desmitis

Desmitis of the cruciate sesamoidean ligaments is rare and difficult to diagnose by ultrasonography because of the location of these ligaments.^{1,2}

Proximal Digital Annular Desmitis

Desmitis of the proximal digital annular ligament or proximal digital annular ligament constriction occurs infrequently (see Chapter 74).^{1,3} Affected horses usually have chronic moderate to severe lameness. Distention of the palmar pouch of the DFTS is usually present, in addition to subtle distention proximal to the palmar annular

ligament of the fetlock. Thickening of the proximal digital annular ligament and skin usually is substantial, with a combined thickness of 4 to 5 mm (normal thickness is 1 to 2 mm) and distention of the DFTS.²¹ Ultrasonographic evaluation of horses with proximal digital annular desmitis often reveals thickening of the synovium of the DFTS, in addition to the proximal digital annular ligament, and may reveal tendonitis of the SDFT or DDFT. Adhesions between the SDFT and the proximal digital annular ligament are suspected when restricted movement of the tendon relative to the proximal digital annular ligament is imaged during a dynamic examination.

Distal Digital Annular Desmitis

See Chapter 74 for a discussion of distal digital annular desmitis.

SOFT TISSUE SWELLING

Soft tissue swelling in the pastern, without tendinous or ligamentous injury, can result from skin irritation caused by liniments, blisters, local therapeutic ultrasound or cold laser treatment, local trauma from a blow, bandaging, or bell (overreach) boots, or from a skin infection. Ultrasonographic findings of thickened anechogenic to echogenic subcutaneous tissues, with normal tendinous and ligamentous structures, are typical for injury or inflammation to the skin and subcutaneous tissues. Thickening of the skin also may be seen in horses with skin irritation or infection. These horses usually respond well to local or systemic antiinflammatory therapy.

TENOSYNOVITIS OF THE DIGITAL FLEXOR TENDON SHEATH

Tenosynovitis of the DFTS is discussed in Chapter 74.

ABNORMALITIES OF THE PASTER JOINT

Lameness and local swelling are two common findings in horses with injuries of the collateral or palmar ligaments of the proximal interphalangeal joint.^{1,3-5,7-9} Swelling is usually primarily medial and lateral, although it can be circumferential. Acute desmitis of the collateral ligaments may be confirmed by ultrasonography, with decreased echogenicity and loss of fiber pattern, with or without an associated avulsion fracture (Figure 82-9).^{1,3-5,7} In horses with more chronic injuries, enthesophyte formation at the origin and the insertion of the collateral ligaments usually is detected. A smoothing of these areas of insertional injury occurs as the desmitis becomes inactive. Similar ultrasonographic findings may be detected in horses with acute (Figure 82-10) and chronic injury (Figure 82-11) to the palmar ligaments of the pastern. These horses have a guarded prognosis for return to full athletic function. Bony proliferative changes associated with “high ringbone” are also easily imaged ultrasonographically.

NEURITIS/NEUROMA

Neuritis of the palmar (plantar) digital nerves results in acute lameness associated with exquisite pain on palpation of the nerves and localized heat and swelling.

Fig. 82-9 • Longitudinal ultrasonographic images of the lateral collateral ligament of the proximal interphalangeal joint of the right hindlimb of horse with moderate lameness and localized swelling. The thickening of the lateral collateral ligament (*large arrows*), the hypoechoic areas of fiber disruption, and the short random fiber pattern seen in the longitudinal view are consistent with desmitis. The distal portion of the proximal phalanx is on the right side of both longitudinal images, and the proximal portion of the middle phalanx is on the left side of both images. The right image is the proximal portion of the lateral collateral ligament, and the left image is the distal portion of the ligament. The small anechoic slit between the proximal and middle phalanges represents the joint space (*small arrow*). There is marked bony proliferative change (irregular bone at the joint space), especially on the proximal aspect of the middle phalanx. Some echogenic subcutaneous thickening is present superficial to the collateral ligament.

Fig. 82-10 • Ultrasonographic images of the left abaxial plantar ligament of the proximal interphalangeal joint in a horse with severe desmitis associated with mild lameness and localized swelling. There is marked enlargement of the ligament. It is hypoechoic and circular to oval in the transverse view (*left*) and has a random fiber pattern in the longitudinal view (*right*). The arrows outline the margins of the ligament. A small amount of echogenic peritendonous subcutaneous tissue is visible.

Ultrasonography shows swelling and decreased echogenicity of the nerve (*Figure 82-12*). Neuromas following palmar digital neurectomy initially appear as focal painful swellings over the stump of the digital nerve. With ultrasonography, the nerve appears enlarged and hypoechoic,

Fig. 82-11 • Ultrasonographic images of the lateral palmar ligament of the proximal interphalangeal joint (*large arrows*) in a horse with chronic severe desmitis and severe enthesopathy. The bony proliferative changes of the proximal phalanx (*small arrows*) in the transverse (*left*) and longitudinal views (*right*) make imaging the ligament in its entirety in either plane impossible at the ligament's origin. The visible portion of the ligament contains hypoechoic areas adjacent to the bony proliferative change in both views and near the ligament's origin in the longitudinal view. The gelding was 2 of 5 degrees lame, with thickening over the lateral and medial aspects of the proximal phalanx, but no heat or local sensitivity was detected.

Fig. 82-12 • Transverse (*left*) and longitudinal (*right*) ultrasonographic images of the right fore medial palmar digital nerve obtained from a horse with a neuroma resulting in acute onset of moderate lameness with local swelling, heat, and exquisite sensitivity to palpation. The enlarged nerve ending (*arrows*), oval to circular shape, is located palmar to the digital artery in the transverse view and superficial to the medial branch of the superficial digital flexor tendon in both views. The cross-sectional area of the nerve is markedly increased. Anechoic and hypoechoic areas disrupt the nerve ending (*arrows*). Notice also the perineural soft tissue thickening.

with perineural soft tissue swelling in horses with an acute neuroma. The neuroma becomes more echogenic and heterogeneous with increasing chronicity of injury. A large amount of perineural echogenic tissue may be present in horses with chronic neuromas.

Chapter 83

Skeletal Muscle and Lameness

Stephanie J. Valberg and Sue J. Dyson

DIAGNOSIS OF SPECIFIC MUSCLE DISORDERS IN THE HORSE

Diagnosis of a particular muscle disorder is best accomplished with a thorough neuromuscular examination. The key components of the examination include the following.

History

A history of stiffness, muscle cramping, pain, muscle fasciculations, exercise intolerance, undiagnosed lameness, weakness, or muscle atrophy may all indicate a muscle disorder. Further characterization requires a detailed account of the horse's performance level, exercise schedule, previous lameness, diet, vaccination history, signs of respiratory disease, duration, severity and frequency of muscle problem, any factors that initiate the muscle problem, and all medications with which the horse is being treated.

Physical Examination

A detailed evaluation of the muscular system includes inspection of the horse for symmetry of muscle mass while standing with forelimbs and hindlimbs exactly square. Any evidence of fine tremors or fasciculations should be noted before palpating the horse. Horses originating in the southwestern United States that have muscle pain and fasciculations should have their ears examined with an otoscope for ear ticks (*Otobius megnini*).¹ The entire muscle mass of the horse should be palpated for heat, pain, swelling, or atrophy comparing contralateral muscle groups. Firm, deep palpation of the lumbar, gluteal, and semimembranosus and semitendinosus muscles may reveal pain, cramps, or fibrosis. The triceps, pectoral, gluteal, and semitendinosus muscles should be tapped with a fist or percussion hammer and observed for a prolonged contracture suggestive of myotonia. Running a blunt instrument such as artery forceps, a needle cap, or a pen over the lumbar and gluteal muscles should illicit extension (swayback), followed by flexion (hogback) in healthy horses. Guarding against movement may reflect abnormalities in the pelvic or thoracolumbar muscles, or pain associated with the thoracolumbar spine (see Chapter 52) or sacroiliac joints (see Chapter 51). The horse should be observed at the walk and the trot for any gait abnormalities, and some horses should be ridden.

Ancillary Diagnostic Tests

Muscle Enzymes

Skeletal muscle necrosis may be identified by determining the activity in blood of serum enzymes or proteins that are

normally present in high concentration within intact muscle cells but leak out into the bloodstream following cell damage. Three enzymes are used routinely to assess muscle necrosis: creatine kinase (CK), aspartate transaminase (AST), and lactate dehydrogenase (LDH). Serum myoglobin has also been used as a marker of acute muscle necrosis.^{2,3} The permeability of the muscle cell membrane, rate of enzyme production, alternate tissue sources of the enzyme, and rate of enzyme excretion/degradation may also influence serum enzyme activities.

Serum Creatine Kinase

Isoforms of CK are found in skeletal muscle (MM), cardiac muscle (MB), and nervous tissue (BB). CK is a relatively low-molecular-weight protein (80,000 Da) that is intimately involved in energy production within the cell cytoplasm. It is liberated within hours of muscle damage, or increased cell membrane permeability, into the extracellular fluid and usually peaks at 4 to 6 hours after muscle injury (half-life [$t_{1/2}$] is 108 min).⁴ A threefold to fivefold increase in serum CK from normal values is believed to represent necrosis of approximately 20 g of muscle tissue.⁵ Rhabdomyolysis results in a proportionately greater increase in the MM isoform than the MB isoform, although some investigators disagree with the tissue specificity of serum CK isoforms in the horse.⁶ Limited elevations in CK (<1000 U/L; high range of normal value = 380 U/L) may accompany training or transport.⁷ Extreme fatiguing exercise (e.g., endurance rides or the cross-country phase of a Three Day Event) may result in CK activities being increased to more than 1000 U/L, but usually less than 5000 U/L. Under these circumstances, serum CK activities rapidly return to baseline (i.e., <350 U/L in 24 to 48 hours). Recumbent horses also may have slightly elevated CK activities that are usually less than 3000 U/L. In contrast, more substantial elevations (from several thousand to hundreds of thousands of units per liter) in the activity of this enzyme may occur with rhabdomyolysis.³

Serum Aspartate Transaminase

Serum AST, previously known as serum glutamic-oxaloacetic acid and aspartate aminotransferase, is a larger-molecular-weight protein that has high activity in skeletal and cardiac muscle and also in liver, red blood cells, and other tissues. Elevations in AST are not specific for myonecrosis, and increases could be the result of hemolysis, muscle, liver, or other organ damage. AST activity increases more slowly in response to myonecrosis than does CK, often peaking between 12 and 24 hours after the insult. In addition, AST is cleared slowly by the reticuloendothelial system and may persist for 2 to 3 weeks after rhabdomyolysis ($t_{1/2}$ is 7 to 10 days).^{4,8}

By comparing serial activities of CK and AST, information concerning the progression of myonecrosis or muscle cell membrane permeability may be derived. Elevations in CK and AST reflect relatively recent or active myonecrosis or muscle cell stress; persistently elevated serum CK indicates that myonecrosis or muscle stress is likely ongoing. Elevated AST activity accompanied by decreasing or normal CK activity indicates that myonecrosis has ceased. The degree of elevation of CK and AST does not necessarily reflect the severity of clinical signs.

Serum Lactate Dehydrogenase

LDH is a tetramer made up of combinations of the M and H subunits, with five isoenzyme forms found in various organs within the body. Electrophoretic separation suggests that the M₄ (LDH₅) and M₃H (LDH₄) isoforms are found predominantly in skeletal muscle. Elevations in LDH may be detected in horses with rhabdomyolysis, myocardial necrosis, and/or hepatic necrosis.⁷ Therefore concurrent measurement of serum CK is necessary to establish that rhabdomyolysis is present.

Myoglobin

Elevation in plasma/serum myoglobin concentrations indicates acute muscle damage. Myoglobin is a low-molecular-weight protein (16,500 Da) that leaks into plasma immediately after muscle damage and is rapidly cleared in the urine by the kidney. Approximately 200 g or more of muscle must be damaged before it is detectable in the urine in people.⁹ Normal serum concentrations in resting horses have been determined by nephelometry (range, 0 to 9 mcg/L), with measured concentrations with rhabdomyolysis ranging from 10,000 to 800,000 mcg/L.^{2,3}

Exercise Response Test

Diagnosing chronic exertional rhabdomyolysis (ER) may be problematic in horses that do not have acute clinical signs and have normal serum AST and CK at rest. In such horses, an exercise challenge can be helpful to detect subclinical ER. In addition, quantifying the extent of rhabdomyolysis during mild exercise is helpful in deciding how rapidly to put a horse back into training. Blood samples should be taken before exercise and 4 to 6 hours after exercise to evaluate peak changes in CK. Serum CK activity measured immediately postexercise will not reflect the amount of damage occurring during the exercise test. Small fluctuations in serum CK activity may occur with exercise from enhanced muscle membrane permeability, particularly if exercise is prolonged or strenuous and the horse is untrained.¹⁰ A submaximal exercise test is often valuable for detecting rhabdomyolysis because it provides more consistent evidence of subclinical rhabdomyolysis than maximal exercise tests.^{3,11} Fifteen minutes of trotting is often sufficient to produce subclinical muscle damage in horses prone to chronic exertional myopathies.¹² If signs of stiffness develop before this, exercise should be concluded. A normal response would be less than a threefold to fourfold increase from basal CK.

Thermography

Thermography may be useful for identification of superficial abnormal temperature changes from muscle damage but has little value in horses with deeper injuries. However, there are many potentially confusing issues such as recent removal of a rug or tack. Careful comparisons of the left and right sides should be made. Muscle inflammation is seen as an area of increased temperature in the skin directly overlying the affected muscle. The most common sites of muscle strain identified thermographically include the longissimus dorsi, the origin or body of the middle gluteal, the insertion of the gluteals on the greater and third trochanters of the femur, biceps femoris, semitendinosus, semimembranosus, and adductor muscles.¹³

Nuclear Scintigraphy

Nuclear scintigraphy is useful for identification of some forms of muscle damage and may alert the clinician to an area of deep muscle damage that had not been suspected based on clinical examination. In human athletes, technetium-99m stannous pyrophosphate has been used to assess the degree of skeletal muscle damage and to delineate areas of damage.^{14,15} It is thought that abnormal uptake of the radiopharmaceutical reflects an early stage of muscle damage from episodic ischemia, which is reversible in some fibers but may lead to muscle necrosis in others.¹⁴

Technetium-99m-methylene diphosphonate (MDP) is taken up in some damaged muscle in the horse and is best seen in the bone (delayed) phase images, that is, 3 hours after injection. Scintigraphy has been used most commonly in horses with a history of poor performance, with or without stiffness after exercise, to confirm a diagnosis of equine rhabdomyolysis.¹⁶ The mechanism of MDP binding is unknown, but the release of large amounts of calcium from damaged muscle or the exposure of calcium binding sites on protein macromolecules in the damaged muscle may be responsible. Diffuse linear areas of increased radiopharmaceutical uptake (IRU) are commonly seen in the caudal epaxial muscles and the muscles of the hind-quarters and thigh in some but not all horses with ER (Figure 83-5). Less commonly there is IRU in the triceps and latissimus dorsi muscles.

The use of scintigraphy for the diagnosis of other muscle injuries has not been documented in the horse, but in one author's experience (SJD) it can be helpful in some horses with either proximal forelimb or hindlimb muscle injuries. Uptake of the radiopharmaceutical tends to be much more focal and much less intense than in horses with rhabdomyolysis. In some, but not all, horses the region of IRU has correlated with a region of increased echogenicity identified ultrasonographically.

Ultrasonography

Diagnostic ultrasonography is potentially useful for identification of muscle trauma and fibrosis, provided that there is physical disruption of the muscle and assuming that one knows where to look. Muscles have a rather typical striated echogenic pattern,^{17,18} but this varies according to the muscle group, and careful comparisons must be made between similar sites in contralateral limbs, in both transverse and longitudinal images. The appearance of muscle is also sensitive to the way the horse is standing and whether the muscle is under tension; therefore it is important that the horse is standing squarely and bearing weight evenly. Muscle fascia appears as well-defined relatively echogenic bands. Care must be taken in identifying large vessels and artifacts created by them.

In an acute injury, muscle fiber disruption is seen as relatively hypoechoic areas within muscle, with loss of the normal muscle fiber striation. The jagged edge of the margin of the torn muscle may be increased in echogenicity. Tears in the muscle fascia may be identified. The muscle defect may be filled by a loculated hematoma that is slowly replaced by hypoechoic granulation tissue. With muscle fiber repair there is a progressive increase in echogenicity. Relatively hyperechoic regions may develop as a result of fibrous scarring, which may result

in long-term gait abnormalities. Hyperechogenic regions causing shadowing artifacts reflect mineralization.

Muscle Biopsy

The routine examination of muscle biopsies has resulted in the identification of a number of specific equine myopathies. To fully characterize a neuromuscular disorder and its rate of progression, muscle fiber sizes, shapes, and fiber type distribution, mitochondrial distribution, polysaccharide staining pattern, neuromuscular junctions, nerve branches, connective tissue, and blood vessels should be examined in frozen sections using a battery of tinctorial and histochemical stains.¹⁹

A number of basic pathological responses of muscle can be identified in formalin-fixed, paraffin-embedded sections. These include inflammation, muscle fiber necrosis, muscle fiber regeneration, variations in muscle fiber sizes and shapes, alterations in the number of cell nuclei, vacuolar change, and proliferation of connective tissue. However, there are many pathological alterations that cannot be detected in formalin-fixed tissue but can readily be seen in histochemical stains of fresh-frozen biopsy samples.²⁰ Histochemical stains of frozen tissue allow muscle fiber types to be distinguished, differentiation between neurogenic and myogenic atrophy, characterization of vacuolar storage material, characterization of inclusion bodies, and assessment of mitochondrial density. In addition, frozen samples may be used for biochemical analysis of substrate concentrations and enzyme activities, as well as DNA isolation.

When considering collection of muscle biopsies, some general guidelines are applicable. Preferably, samples should be collected from what is considered abnormal/diseased muscle. A 6-mm outer diameter (Jorgen KRUSE A/S, Langeskov, Denmark) percutaneous needle biopsy technique can be used to obtain small muscle samples through a 1.5-cm skin incision using a local anesthetic solution subcutaneously. If this technique is used, enough muscle should be obtained to form a 1.5-cm² sample at a minimum. However, these samples do not tolerate well shipment to an outside laboratory. The optimum biopsy for shipment of histopathological tissues to a laboratory is collected using surgical or open techniques and performed under local analgesia. Care must be exercised to infiltrate only the subcutaneous tissues, not the muscle, with the local anesthetic solution. The objective is to obtain approximately 2-cm³ of tissue; hence a suitably long skin incision is required. Subsequently two parallel incisions 2 cm apart should be made longitudinal to the muscle fibers with a scalpel. The muscle should only be handled in one corner using forceps, and care should be taken not to crush the tissue. The muscle sample is then excised by transverse incisions 2 cm apart, and the tissue is fixed appropriately.

Samples submitted for routine histopathology can be placed in formalin. Samples for histochemical analysis require fixation in isopentane (methylbutane) chilled in liquid nitrogen to ensure rapid freezing and minimization of freeze artifact. In the field, where freezing is not possible, fresh samples wrapped in gauze slightly moistened with saline can be shipped in a water-tight hard container on icepacks to specialized laboratories. Samples that potentially may be used for biochemical analysis should be

immediately frozen in liquid nitrogen. Samples for electron microscopy (EM) require appropriate fixation in glutaraldehyde preparations. Ideally, thin sections of muscle for EM should be clamped *in vivo* to maintain fibers at a resting length before they are excised. However, if pathology other than the alignment of thick and thin myofilaments is to be investigated, small muscle pieces can be excised and placed directly in appropriate EM fixative.

Responses of strips of fresh muscle to stimuli such as caffeine, halothane, and a variety of other agents can be performed on site by specialized laboratories, but these tests are largely research tools.^{21,22}

Electromyography

A specific diagnosis of the cause of muscle atrophy, muscle fasciculations, or myotonic dimpling after tapping the muscle can be aided by performing electromyography (EMG). EMG of normal skeletal muscle shows a brief burst of electrical activity when the needle is inserted in muscle and then quiescence, unless motor units are recruited (motor unit action potentials), or the needle is very close to a motor endplate (miniature endplate potentials). Normal muscle shows little spontaneous electrical activity unless the muscle contracts or the horse moves. Motor unit action potentials can be evaluated to assess amplitude, duration, phase, and number of phases. Myopathic changes include a decrease in duration and amplitude of motor unit action potentials.^{23,24} Horses with abnormalities in the electrical conduction system of muscle, or denervation of motor units, show abnormal spontaneous electrical activity in the form of fibrillation potentials, positive sharp waves, myotonic discharges, or complex repetitive discharges.

Based on the information obtained on neuromuscular examination and muscle biopsy, a diagnosis can usually be obtained. The following classification system may be helpful to narrow down rule-outs for muscle disease in horses:

- I. Nonexercise-associated rhabdomyolysis
 - A. Inflammatory myopathies
 1. Immune-mediated
 - a. Infarctive hemorrhagic purpura
 - b. Immune-mediated myopathy
 2. Infectious
 - a. Clostridial myositis
 - b. *Streptococcus equi* myositis
 - c. Anaplasma myositis
 - d. Viral myositis
 - e. Sarcocystis myositis
 - B. Nutritional myopathy
 1. Vitamin E and selenium deficiency
 - C. Toxic myopathy
 1. Ionophore toxicity
 2. Pasture myopathies
 - a. Rayless goldenrod/white snakeroot
 - b. *Cassia occidentalis*
 - c. Atypical myoglobinuria
 - D. Traumatic myopathy
 1. Compressive anesthetic myopathy
 2. Trauma
 - E. Metabolic myopathy
 1. Glycogen branching enzyme deficiency in Quarter Horses

2. Type 1 and type 2 polysaccharide storage myopathy
3. Malignant hyperthermia
- II. Exertional rhabdomyolysis
 - A. Focal muscle strain
 - B. Extrinsic (sporadic) tying-up
 1. Dietary imbalances, vitamins, minerals, electrolytes
 2. Exercise in excess of training
 3. Exhaustion syndrome
 - C. Intrinsic (chronic) tying-up
 1. Type 1 polysaccharide storage myopathy
 2. Type 2 polysaccharide storage myopathy
 3. Malignant hyperthermia
 4. Recurrent ER
 5. Idiopathic chronic ER
- III. Exertional myopathy with normal CK
 - A. Mitochondrial myopathy
- IV. Muscle atrophy
 - A. Myogenic atrophy
 1. Disuse
 2. Cachexia
 3. Cushing's disease
 4. Immune-mediated myositis (rapid atrophy)
 5. Type 2 polysaccharide storage myopathy
 6. Severe rhabdomyolysis
 - B. Neurogenic atrophy
 1. Equine protozoal myelitis
 2. Local nerve trauma
 3. Equine motor neuron disease
- V. Muscle fasciculations
 - A. Pain, fear
 - B. Electrolyte abnormalities
 - C. Hyperkalemic periodic paralysis
 - D. *O. megnini* ear tick infestation
 - E. Myotonic dystrophy
 - F. Stiff horse syndrome
 - G. Equine motor neuron disease
 - H. Focal nerve irritation

MUSCULAR PAIN, STRAIN, AND TEARS

The role of muscle pain and injury in lameness and poor performance in the horse is rather poorly recognized. In human athletes, muscle fatigue, muscle stiffness, and muscle soreness are well-recognized entities, although the pathological processes in the absence of detectable structural abnormalities are not completely understood. Increased intramuscular pressure may be associated with muscle pain after prolonged vigorous exercise in human athletes.¹⁴

Delayed-onset muscular stiffness or soreness (DOMS) is recognized in people as pain that develops 24 to 48 hours after unaccustomed use of certain muscles and usually resolves spontaneously, assuming the muscles are not over-worked again.²⁵ Continued overstress may result in structural damage to myofilaments. However, specific training involving the activity that provoked the original DOMS decreases the amount of soreness associated with that condition over time.

Muscle soreness in the pectoral region after repeated jumping efforts is commonly recognized, especially in event horses several hours after completing the cross-country

phase of a Three Day Event.²⁶ It seems to improve with massage.

Muscle fiber tearing and hemorrhage can result in acute muscular pain in human athletes. A palpable defect or swelling can be detected in superficial muscles. For deeper muscles, ultrasonography is required for accurate diagnosis.

Muscle fibrosis and mineralization have been well documented in the horse following tearing of the semi-membranosus and semitendinosus muscles (see Fibrotic Myopathy section, page 558), but acute lesions here and elsewhere in the limbs have been poorly documented.²⁷⁻²⁹ The use of diagnostic ultrasonography^{17,18} has helped in the diagnosis of both acute and more chronic muscle lesions, but diagnosis often remains a challenge because of the deep location of some affected muscles and the lack of localizing clinical signs.

In one author's (SJD) experience, the most commonly recognized muscle injury sites in the forelimb include biceps brachii, brachiocephalicus, the pectorals, and the musculotendinous junction of the superficial digital flexor (Figures 83-1 to 83-4). In the hindlimb, semimembranosus and semitendinosus, adductor, gracilis, gluteal, and gastrocnemius muscle injuries have been recognized most frequently. Acute muscle tearing and hemorrhage can result in severe pain and lameness and other clinical signs mimicking colic. Swelling around the damaged muscle, assuming it is superficial, may not appear until 24 to 48 hours later.

Muscle tension and spasm in the thoracolumbar region are well-documented sources of pain contributing to poor performance in association with primary hindlimb lameness, but primary muscle pain in this region has often tended to be overlooked by many veterinarians, although recognized by physiotherapists. Localized muscle soreness and the interpretation of abnormal sensitivity of acupuncture points are potentially confusing. Protective muscle spasm may also develop secondary to a primary lesion of either the thoracolumbar spine or the sacroiliac region (see Chapters 49 to 52).

Jeffcott et al³⁰ demonstrated that injection of lactic acid into the left longissimus dorsi muscles could significantly diminish performance of Standardbred (STB) trotters worked at speed on a treadmill, although changes in gait were subtle.

One author (SJD) has seen a number of horses that had suddenly lost performance during competition or training, either following a particularly extravagant jump or after an awkward jump. The horses had subsequently become reluctant either to jump or to gallop downhill. Clinical examination revealed intense muscle spasm in the caudal thoracic and lumbar regions, with associated pain. Manipulation to release muscle spasm resulted in relief of pain and rapid restoration of normal performance. Acute back muscle pain may also be induced by a fall.

Localized back muscle soreness is readily induced by a poorly fitting saddle. It may also be caused by a rider who either sits crookedly or is unable to ride completely in balance with the horse. This may be because of the ineptitude of the rider or the shape of the saddle and the way in which it sits on a particular horse and thus positions the rider. Such muscle pain is usually localized to the saddle area and may be associated with slight soft tissue swelling.

Fig. 83-1 • A and B, Longitudinal ultrasonographic images of the muscles at the base of the neck on the left and right sides of an advanced-level event horse with restricted forelimb gait (*left* images indicate left side; *right* images indicate right side). The horse had severe pain and tension in the strap muscles at the base of the neck on the left side and slight muscle atrophy. Note the increased echogenicity of the deeper muscle on the left side compared with the right. The horse was treated by H-wave stimulation that resulted in progressive relief of the muscle spasm and clinically significant improvement in gait and ability to jump.

Thermographic examination may be helpful to demonstrate to an owner the associated localized inflammation. Pressure measurements can also be used (see Figure 117-6), although there is some variability in the accuracy of different commercially available systems.

Diagnosis

History and Clinical Examination

It is important to establish whether there was a history of a fall or other traumatic event, the duration of clinical signs, whether swelling was noted, and whether the horse had exhibited lameness or had performed poorly.

The detection of muscle swelling from recent trauma or loss of muscle bulk as a result of fibrosis, chronic injury, or atrophy requires the horse to stand completely squarely, bearing weight evenly on all limbs and looking straight

ahead. The horse should be appraised visually and by careful, systematic palpation, looking for defects in the muscle, muscle swelling, areas of abnormal muscle firmness from fibrosis, muscle tension, or spasm, and areas of pain.

In an acute injury resulting in muscle tearing or rupture, it may be possible to palpate a defect in the very early stages, but this will become filled with hemorrhage, inflammatory exudate, and edema. Careful palpation should enable detection of most acute superficial muscle injuries, but localization of deeper muscle injury may be more difficult. Identification of chronic muscle strain is more challenging because clinical signs are more subtle. The horse must be as relaxed as possible to assess properly the response to firm and deep palpation. If the muscle is sore, the horse may react by increasing tension in anticipation of pain or by pulling away. There may be “knots” within the area of damaged muscle.

Fig. 83-2 • Transverse ultrasonographic images of the right (*left*) and left (*right*) gracilis muscles of a 12-year-old Thoroughbred cross event horse with acute-onset right hindlimb lameness of 6 days' duration, with slight swelling of the muscle, pain on palpation, and diffuse edematous swelling in the crus. At the time of lameness onset, the horse showed signs attributed to colic. A focal region of increased echogenicity in the right gracilis muscle is caused by muscle fiber tearing and hemorrhage.

Fig. 83-3 • Transverse ultrasonographic image of the left brachiocephalicus muscle of a Grand Prix dressage horse that showed left forelimb lameness only when performing lateral movements, such as half pass. The lameness was not altered by any local analgesic technique. There is a focal area of increased echogenicity, caused by muscle fibrosis, resulting in acoustic shadowing.

The neck, limbs, and thoracolumbar region should be moved passively to detect any limitations in movement or pain induced by movement. The horse should be observed moving at both the walk and the trot to identify any characteristic gait abnormalities, such as an abnormal hind foot placement from fibrotic myopathy (see Chapter 48) or sinking of a front fetlock as a result of rupture at the musculotendinous junction of the superficial digital flexor (see Chapter 13). However, it must be borne in mind that muscle soreness resulting in compromise of performance may not result in overt lameness because pain may only be induced when the muscle contracts strongly or is stretched maximally. Pain associated with a brachiocephalicus muscle in a dressage horse may only be evident in particular movements such as half pass (see [Figure 83-3](#)).

Fig. 83-4 • Longitudinal ultrasonographic image of the cranial aspect of the antebrachium of a 7-year-old hunter. The horse had developed acute-onset lameness 3 months previously, associated with substantial soft tissue swelling on the cranial aspect of the antebrachium. The extensor carpi radialis muscle is enlarged greatly and has hypoechoic and hyperechoic regions, with little normal muscle architecture.

A show jumper with sore gluteal muscles may not push off as strongly with the affected limb, resulting in the hindquarters drifting toward the ipsilateral side as the horse jumps.

Muscle Stimulation

Muscle-stimulating machines can be helpful in the identification of superficial muscle injuries. Intermittent electrical stimulation of focal areas within a muscle results in muscle contraction and relaxation. The strength of stimulus can be varied. Horses vary in sensitivity and tolerance of the procedure, so careful comparisons must be made between the left and right sides. Damaged muscle tends to respond greater to lower stimulus strength, and contraction and relaxation are less smooth and may induce pain.

Thermography, Nuclear Scintigraphy, and Ultrasonography

Thermography, nuclear scintigraphy, and ultrasonography are discussed on pages 819 and 820.

Muscle Enzymes

Determination of serum muscle enzyme concentrations is rarely of value in identification of muscle soreness or trauma but is useful for detecting horses with rhabdomyolysis (see page 813).

Treatment

The aims of treatment include repair of damaged muscle, relief of both muscle spasm and pain, restoration of normal circulation, minimization of fibrous scar formation, and remobilization of muscles. The precise mode of treatment will depend on the type of muscle injury and the stage of injury and repair. Treatment modalities include laser,^{31,32}

therapeutic ultrasound,³¹ H wave, transcutaneous electrical stimulation, electromagnetic therapy,³³ massage,²⁶ passive stretching combined with box rest, and a graduated, controlled exercise program. Relief of acute muscle spasm may require chiropractic manipulation. During return to work, the exercise program must be carefully moderated according to the site of the injury and to avoid overstress in the early stages of repair while encouraging a progressive increase in strength. These subjects are discussed more fully elsewhere (see Chapters 92 through 96).

Prevention

Because equine muscle injuries are poorly recognized there has been little work on prevention. However, there is evidence to document the beneficial effects of warm-up before strenuous exercise.³⁴⁻³⁶ Warm-up enhances blood flow to active muscle and increases muscle temperature. This results in better oxygen delivery to exercising muscle, improved enzyme function, and increased range of motion. The best warm-up program for each type of exercise remains poorly defined; however, warm-up should aim to prepare the physiological systems, without contributing to excessive heat generation or fatigue.

EXERTIONAL RHABDOMYOLYSIS

ER has numerous etiologies and is a common complex cause of poor performance. About 3% of exercising horses had an episode of ER in the past 12 months.³⁷ It occurs in a variety of breeds, including draft breeds, Warmbloods, Thoroughbreds (TB), STBs, Arabians, Morgans, Quarter Horses, Appaloosa, American Paint horses, and many more.³⁷⁻⁴¹ In draft breeds, ER can be particularly debilitating, and terms such as *Monday morning disease*, *azoturia*, or *paralytic myoglobinuria* are used.⁴² A milder syndrome occurs in lighter breeds, and the terms *tying-up*, *set fast*, *myositis*, and *chronic intermittent rhabdomyolysis* are used to describe muscle necrosis or muscle cell stress following any form of exercise in the lighter horse breeds.^{43,44} Several specific causes have been identified for ER. Otherwise successful athletic horses may have a sporadic episode of ER from extrinsic causes such as dietary imbalances, concurrent respiratory infections, and inappropriate training regimens. In horses chronically afflicted with ER there may be an intrinsic dysfunction of muscle metabolism or muscle contraction.

Sporadic Exertional Rhabdomyolysis

The most common extrinsic cause of sporadic ER is exercise that exceeds the horse's underlying state of training.⁴⁴ Horses that are advanced too quickly in training, horses that are only ridden sporadically while being continually fed full rations, and horses performing strenuous exercise such as racing or endurance riding without sufficient conditioning commonly develop rhabdomyolysis. In addition, rhabdomyolysis may be more common in horses exercising during an outbreak of respiratory disease. Both equine herpesvirus-1 and equine influenza virus have been implicated as causative agents.^{38,45}

Clinical Signs

Classically, horses lose impulsion and develop a stiff, stilted gait, particularly involving the hindquarters during

exercise. There is excessive sweating and a high respiratory rate from pain. The horse may be unable to walk forward after resting because of firm painful muscle contractures involving the back and hindquarters. Signs are most commonly seen after 15 to 30 minutes of light exercise.^{40,46} A horse with severe rhabdomyolysis shows signs of colic, becomes recumbent, and develops occult myoglobinuria. The urine may be discolored and has an abnormal smell. Attempts to move more severely affected animals may result in extreme pain, obvious anxiety, and exacerbation of the condition.

ER is often symmetrical, involving gluteal, biceps femoris, semitendinosus, and semimembranosus muscles. Forelimbs are less commonly overtly affected. ER may accompany the exhaustion syndrome in endurance horses with concurrent evidence of a rapid heart rate, dehydration, hyperthermia, synchronous diaphragmatic flutter, and collapse.⁴⁷ Muscle contractures are not always consistent in either endurance horses or event horses with ER.

Diagnosis is usually obvious based on the clinical signs, but measurement of serum muscle enzyme activities provides an assessment of the severity of muscle damage and confirms the diagnosis. The degree of elevation of muscle enzyme activity does not necessarily reflect the severity of clinical signs.

Treatment of Acute Rhabdomyolysis

If an attack has occurred during exercise some distance from where the horse is normally stabled, the horse should not be made to walk home. It should be transported back home or left in a nearby stable. If an attack has occurred at a competition, the horse should be treated there and should not be transported home over a long distance until at least 24 to 48 hours later.

The objectives of treatment are to relieve anxiety and muscle pain, as well as to correct fluid and acid-base deficits. Acetylpromazine (0.04 to 0.07 mg/kg), an α -adrenergic antagonist, is helpful in relieving anxiety and may increase muscle blood flow. Its use is contraindicated in dehydrated horses. Alternatively, xylazine (0.4 to 0.8 mg/kg) may provide short-term relief from anxiety. In horses with extreme pain, detomidine (0.02 to 0.04 mcg/kg) combined with butorphanol (0.01 to 0.04 mg/kg) provides excellent sedation and analgesia. Nonsteroidal antiinflammatory drugs (NSAIDs) such as ketoprofen (2.2 mg/kg), phenylbutazone (2.2 to 4.4 mg/kg), or flunixin meglumine (1.1 mg/kg) provide additional pain relief. Analgesic treatment is continued to effect, but most horses are relatively pain free within 18 to 24 hours.

Intravenous or intragastric dimethyl sulfoxide (as a <20% solution) can be used as an antioxidant, antiinflammatory, and osmotic diuretic in severely affected horses. Corticosteroid administration is advocated by some veterinarians in the acute stage. If the horse is recumbent, methyl prednisolone succinate (2 to 4 mg/kg intravenously [IV]) should be given once. Muscle relaxants such as methocarbamol (5 to 22 mg/kg, IV slowly) seem to produce variable results, possibly depending on the dosage used. The administration of dantrium sodium (2 to 4 mg/kg orally [PO]) in severely affected horses may decrease muscle contractures and possibly prevent further activation of muscle necrosis. This can be repeated in 4 to 6 hours.

Severe ER can lead to renal compromise from ischemia and the combined nephrotoxic effects of myoglobinuria, dehydration, and NSAIDs. The first priority in horses with hemoconcentration, or myoglobinuria, is to reestablish fluid balance and induce diuresis. In horses with mild rhabdomyolysis, administration of fluids via a nasogastric tube may be adequate, but generally fluids are better given intravenously. Balanced polyionic electrolyte solutions are best. If severe ER is present, then isotonic saline or 2.5% dextrose in 0.45% saline may be necessary because horses often have hyponatremia, hypochloremia, and hyperkalemia. If hypocalcemia is present, then supplementing intravenous fluids with 100 to 200 mL of 24% calcium borogluconate is recommended, but serum calcium should not exceed a low normal range. Affected horses are usually alkalotic, making bicarbonate therapy inappropriate.⁴⁸

Ten liters of fluids may be given rapidly. The total fluid replacement is based on an estimation of the degree of dehydration and the clinical response: if the horse is mildly dehydrated (5%), give 10 L fast and then 15 L over the next 4 to 6 hours; if dehydration is severe (20%), give 10 L fast and then 50 L at 4 L/h. If the horse is recumbent, consider using at least two intravenous giving sets and infusing into both the jugular and the cephalic veins. Suture the catheters in place.

Ideally, reassessment of the packed cell volume and concentrations of total plasma protein and serum electrolytes after the initial period of therapy should provide a successful guide for the therapeutic regimen. However, in the practical situation, the clinical response to therapy is usually an adequate indicator. In severely affected horses, regular monitoring of blood urea nitrogen and/or serum creatinine is advised to assess the extent of renal damage. Diuretics are usually contraindicated unless the horse is in oliguric renal failure.

Horses should be stall rested on a hay diet for a few days. Small paddock turnout in a quiet area for a few hours twice a day is then helpful. Horses may be handwalked at this time but not for more than 5 to 10 minutes at a time. For horses with extrinsic (sporadic) ER, rest with regular access to a paddock should continue until serum muscle enzyme activities are normal. Training should be resumed gradually, and a regular exercise schedule that matches the degree of exertion to the horse's underlying state of training should be established. Avoid lunging exercise until the horse is back in normal work. If the horse has a day or several days off, the dietary energy concentrations should be reduced accordingly.

Chronic Exertional Rhabdomyolysis

Horses that have repeated episodes of ER from a young age, or from the time of purchase, or when they are put back into training after a long period of rest may have a chronic dietary imbalance or underlying intrinsic abnormality of muscle function. Chronic forms of ER are seen in many breeds of horses, including draft horses, Warmbloods, Quarter Horses, American Paint horses, Appaloosas, TBs, Arabians, STBs, Morgans, and crossbreds.^{39,44,49-55} Many of the horses with intrinsic muscle defects will have repeated episodes of rhabdomyolysis with minimal exercise, even when the dietary and training recommendations for sporadic ER are followed. Three specific intrinsic causes of ER have been identified to date: recurrent exertional

rhabdomyolysis (RER),⁵⁶ type 1 polysaccharide storage myopathy (PSSM),^{57,58} and type 2 PSSM.⁵⁹ It is likely that there are other specific causes that have yet to be identified (idiopathic chronic ER). In all these intrinsic forms of chronic ER, it appears that there are specific environmental stimuli that are necessary to trigger muscle necrosis in genetically susceptible animals.^{46,56} Horses cannot be cured of a susceptibility to this condition, but if the specific disease is identified, changes in management can be implemented to minimize episodes of rhabdomyolysis.

Chronic Dietary Imbalance

Horses consuming a high-grain diet appear to be more likely to develop ER than horses fed a low-grain or fat-supplemented diet.^{46,56,60} The grain itself may not be responsible for rhabdomyolysis; however, high starch intake may trigger rhabdomyolysis in horses with particular myopathies such as RER and PSSM.

Electrolyte depletion in horses can occur from dietary deficiency and losses in sweat with strenuous exercise. Sodium, potassium, magnesium, and calcium play key roles in muscle fiber contractility. With severe acute electrolyte depletion, such as that found after endurance exercise, serum electrolytes may be below normal ranges.⁴⁷ With chronic dietary depletion, however, serum concentrations may not reflect total body electrolyte imbalances.^{61,62} Work by Harris et al^{61,62} established renal fractional excretions as a technique to evaluate electrolyte concentrations in horses with chronic ER. Blood and urine samples are obtained concurrently, and creatinine and electrolyte concentrations are measured in both. [Serum creatinine]/[urine creatinine] multiplied by the reciprocal for urine and serum electrolyte concentrations $\times 100$ provides the fractional excretion of a particular electrolyte. It can be difficult to obtain consistently representative renal fractional excretions of electrolytes in horses from catheterized samples.⁶³ In the United Kingdom, a number of horses with chronic ER had low fractional excretions of sodium, and daily dietary supplementation of 60 g (2 oz) of NaCl resulted in abatement of clinical signs. Other horses had high phosphorus excretion, suggesting a dietary calcium/phosphorus imbalance, and decreasing bran while providing a daily calcium supplement (60 g of CaCO₃) was helpful in reducing clinical signs of ER.⁶² Hypokalemia was suggested to play a role in chronic ER, although it is not a common finding in horses consuming adequate quantities of forage.^{64,65} Supplementation with good quality forage or 30 g of KCl/day ("lite" salt) is recommended for horses with low renal fraction excretion of potassium.

Another postulated cause of ER is the increased generation of free radicals from oxidative metabolism associated with exercise. Selenium, acting via the enzyme glutathione peroxidase, and vitamin E, acting within the lipid component of cell membranes, scavenge free radicals and prevent lipid peroxidation of cell membranes. Primary selenium deficiency is common in young horses living in areas with selenium-deficient soil; however, it has rarely been demonstrated as a cause of ER.⁴⁰ In fact, many racehorses with chronic ER have higher concentrations of selenium and vitamin E from zealous dietary supplementation by the owner.⁶⁶ Riding horses, however, that are not on green pasture for 2 or more years may develop a deficiency of vitamin E, which could contribute to muscle soreness. It is

not known whether horses that experience repeated episodes of ER may generate more free radicals than normal horses. A higher generation of free radicals in horses with chronic ER may explain the perceived benefit of repeated administration of selenium and vitamin E in TB horses with chronic ER.⁶⁷ Adequate values are more than 0.07 mcg/mL for blood selenium and more than 2.0 mcg/mL for serum vitamin E.

Recurrent Exertional Rhabdomyolysis

About 5% to 10% of TB racehorses develop ER during a racing season, and 75% of these horses have more than four episodes in 4 months.⁵⁵ Approximately 6% of National Hunt horses⁶⁸ and 13% of polo horses develop ER.⁶⁹ Horses with a nervous disposition, especially fillies, are highly predisposed.⁵⁶ Research studies suggest that a subset of TB horses with chronic ER have RER.^{11,12,22} RER appears to be an inherited, intermittent, stress-induced defect in the regulation of muscle contraction.^{12,22} A breeding trial using TB horses with RER confirmed that the characteristic abnormality in muscle contracture is inherited in an autosomal dominant fashion.⁷⁰ Recurrent episodes of rhabdomyolysis in STBs and Arabian horses may be from a similar abnormality, but this has not been confirmed. A heritable basis for RER in STBs was supported by equine lymphocyte antigen profiles in affected horses.⁵⁰

Factors that trigger RER in susceptible horses include gender, temperament, excitement, stress, dietary starch, exercise duration/intensity, season, and lameness.^{40,41,56,71} Females are most commonly afflicted with RER (67% female, 33% male), particularly those that are 2 years of age and in race training.^{56,71} Nervous horses are five times more likely to develop RER, and horses with lameness are four times more likely to develop RER. Susceptible horses receiving more than 5 kg of concentrate feed (oats, corn, molasses mix) are more likely to develop RER than those receiving 2.5 kg of concentrate feed/day.⁵⁶ Dietary effects of high carbohydrate in horses with RER may in part be related to the psychogenic effects of grain on excitability. In horses with RER, glycogen storage does not increase substantially.^{60,72} Inclement weather has been cited as a trigger of RER, and the condition is reported more commonly in the autumn and winter in the United Kingdom.⁴⁰

A contribution of reproductive hormones to triggering RER was postulated because the incidence appears to be highest in mares.^{41,56,71} Many owners report that episodes of RER occur most commonly during estrus, but in one study of racehorses, no direct correlation was shown between progesterone fluctuations and serum CK activity.⁷³ It is likely that the estrus cycle is one of many factors that combine to trigger RER in susceptible horses. Many racetrack practitioners report that the incidence of RER declines when susceptible mares are treated with testosterone. Hypothyroidism and lactic acidosis were suggested as a cause of RER but have never been substantiated.^{3,60,74-76}

Clinical Signs

Horses with RER have intermittent elevations in serum CK activity.^{3,11,67,68} Episodes of muscle stiffness, sweating, and firm muscle contractures often occur in horses once they become fit and are frequently associated with excitement at the time of exercise. In TBs, RER occurs most frequently during training when horses are held to a slow gallop.⁵⁶ In

STBs, RER often occurs 15 to 30 minutes into jogging.³ Obvious clinical signs are rare after racing. A history of poor performance and elevated serum AST and CK may be the only presenting complaints in some horses. Older TBs used as riding horses may have very intermittent episodes of RER associated with layup of fit horses. Event horses often develop clinical signs after the steeplechase phase or in the "10 minute box" of a long-format Three Day Event, or less commonly after warm-up for the cross-country phase of a short-format Three Day Event or during the cross-country phase. Muscle stiffness, reluctance to collect, and lack of power may be present on a continual basis between episodes in some of these older horses. Arabian horses often develop clinical signs with little exertion, frequently in association with excitement.

In some riding horses, the clinical signs of a mild attack may be very subtle and are easily missed by the rider. The horse is maintained in work and may actually experience daily episodes resulting in cumulative muscle damage (Figure 83-5).

Diagnosis

A submaximal exercise test (page 819) is useful for identification of RER in a horse with a history of poor performance unrelated to signs typical of tying-up. Nuclear scintigraphy (page 819) may demonstrate IRU in the affected muscles of some, but not all, affected horses.

Muscle biopsies from horses with RER that are in training have a characteristic histological appearance (Figure 83-6). These horses have increased numbers of centrally located nuclei in mature muscle fibers. They may have evidence of varying stages of muscle degeneration and regeneration, and they have normal to slightly increased muscle glycogen staining.¹¹ Histopathological changes are often lacking in horses that have been laid up for a period before biopsy. In addition, RER is characterized by abnormal sensitivity of intact muscle bundles to contractures induced by the addition of caffeine or halothane to a muscle bath.^{21,22} Elevated myoplasmic calcium concentration was reported in muscle of horses with acute ER⁷⁷ and

Fig. 83-5 • Dorsal scintigraphic image of the pelvic region of an 8-year-old show jumper mare with a history of poor performance and reluctance to work. Cranial is at the top. There are linear areas of moderately increased radiopharmaceutical uptake in the muscles, associated with chronic, recurrent exertional rhabdomyolysis.

Fig. 83-6 • Cryostat-cut sections of a biopsy of the semitendinosus muscle of a Thoroughbred with recurrent exertional rhabdomyolysis (RER) stained with hematoxylin and eosin. Note the presence of centrally located nuclei in mature muscle fibers. This is a common feature of biopsies of horses with RER.

in myoblasts derived from TBs with RER.¹² There are physiological similarities between the contracture results of RER and contracture tests for malignant hyperthermia (MH). Biochemical studies of isolated muscle cell membranes⁷⁸ and linkage analysis⁷⁹ do not support an identical biochemical basis for MH and RER. The increased halothane sensitivity of the muscles in RER horses may explain why many TBs with RER develop rhabdomyolysis under halothane anesthesia.⁸⁰

Management

In the past, horses have been box stall rested for several weeks following an episode of RER. It is our opinion that this is counterproductive and increases the likelihood that the horses will develop rhabdomyolysis when put back into training. The initial muscle pain usually subsides within 24 hours of acute RER, and daily turnout in a small paddock can be provided at this time. Subsequently, a gradual return to performance is recommended once serum CK is close to normal range.

Prevention

Prevention of further episodes of RER in susceptible horses includes standardized daily routines and providing an environment that minimizes stress. This should include desensitizing horses to stressful situations, moving to a quiet area of the barn, regular turnout, and positioning near compatible horses. Daily exercise is essential, whether in the form of turnout, walking on a horse walker, lunging, or riding. There should be a long, slow, warm-up period.

The diet should be adjusted to include a balanced vitamin and mineral supplement, high-quality hay (but not alfalfa), and a minimum of soluble carbohydrates (<3 kg of high-starch concentrate). Postexercise serum CK activity in horses with RER is influenced by the amount of energy horses are fed daily, as well as the composition of the diet. When 500-kg TBs with RER were fed 88 MJ (21 Mcal) of energy and exercised for 30 minutes a day, serum CK activity after exercise was within the normal range. There was no measurable effect of feeding a starch-based (2.5 kg of an oat, corn, molasses mix) or a fat-based (2.3 kg of rice bran; 20% digestible energy [DE] from fat) supplement with

hay on muscle necrosis.⁶⁰ However, when the energy level was increased to a level that was closer to what is normally fed to racehorses (117 MJ or 28 Mcal), the source of energy had a significant effect on postexercise CK activity. Horses fed a high proportion of energy in the form of starch (5 kg of oat, corn, molasses mix) had significantly higher CK levels after exercise than horses fed 25% of total DE as fat (Re-Leve, Hallway Feeds, Lexington, Kentucky, United States).⁷² Therefore it would appear that TBs susceptible to RER that are in moderate to high intensity training should be fed concentrate feeds that are relatively low in starch (<20% DE) and high in fat (20% DE or a feed that is 10% to 12.5% fat by weight) to minimize postexercise muscle damage. Vegetable oils can be used to supplement low-starch feeds (a maximum of 600 mL/day, with 800 U of vitamin E). However, it is difficult to achieve adequate caloric intake for TBs in race training by adding vegetable oil to low-starch feeds such as hay cubes. For hard keepers, a complete low-starch, high-fat pelleted feed containing vegetable oils and/or rice bran works well and provides a balanced ration. One such feed, Re-Leve, has been shown to lower serum CK activity in exercising TBs with RER. No more than half of the total of forage should be fed as alfalfa: lower-starch hays such as grass or meadow, timothy, brome, or oat hay are preferable. Corn and barley should be avoided because they are particularly high in starch.

The use of low doses of acetylpromazine tranquilizers (0.005 to 0.01 mg/kg) 30 minutes before exercise is believed to help some nervous or excitable horses. Long-acting tranquilizers such as fluphenazine have been used successfully by some practitioners. Dantrolene (2 to 4 mg/kg PO) given 1 hour before exercise has proven to be effective in preventing RER in some horses.^{81,82} Dantrolene is used to prevent MH in people and swine by decreasing the release of calcium from the calcium release channel. Phenytoin has also been advocated as a treatment for horses with RER.⁸³ Dosages are adjusted in horses to maintain serum levels of 8 to 10 mcg/mL. Initial doses begin at 6 to 8 mg/kg PO for 3 to 5 days. Doses can be increased by 1-mg/kg increments every 3 days until RER is prevented but should be cut back if horses appear drowsy. If possible, serum phenytoin concentrations should be assessed regularly at the initiation of treatment. Phenytoin acts on a number of ion channels within muscle and nerves, including sodium and calcium channels. Unfortunately, long-term treatment with dantrolene or phenytoin is expensive, and efficacy has not been established.

In some mares in which episodes of RER coincide with estrus, suppression of estrus using progesterone implants or injections may be helpful. This should be done in conjunction with dietary and training alterations. Anecdotal information from racehorse trainers suggests injection with testosterone cypionate decreases RER in TB mares; however, this may be a banned substance in many racing districts.

The above management is effective in reducing RER in many horses, but some remain intractable. Nervous young racing fillies and older riding horses, especially event horses, present the greatest challenge in management.

Polysaccharide Storage Myopathy

A subset of horses with chronic ER have a storage disorder characterized by the accumulation of glycogen and an abnormal polysaccharide in skeletal muscle.⁵⁸ Abnormal

polysaccharide accumulation occurs in a variety of European and North American breeds of riding and driving horses that have a history of muscle stiffness and increased serum CK activity after exercise.^{51,53,84,85}

Recently an autosomal dominant gain-of-function mutation was identified in the glycogen synthase gene (*GYS1*) in Quarter Horses with PSSM.⁵⁷ This mutation is found in at least 20 different breeds of horses in Europe and North America. Affected breeds include Quarter Horses; American Paint horses; Appaloosas; draft horses, including American Cream, Belgian, Percheron, Cob Normande, Treopard, Haflinger, Morgan, Mustang, Rocky Mountain Horse, and Tennessee Walking Horse breeds; mixed breed horse; Cobs; Hanoverians; Rheinlander; and Warmbloods of unspecified type.^{53,59} Because some horses with elevated muscle glycogen content do not possess the *GYS1* mutation, PSSM is now subdivided into type 1 and type 2.⁵⁹ Type 1 PSSM refers to horses with the *GYS1* mutation. The prevalence of the PSSM from the *GYS1* mutation ranges from 8% in Quarter Horses and Paints⁵² to 36% in Belgian draft horses,⁵⁴ with no reported cases in the few TBs, STBs, and Arabians tested.^{53,59} Type 2 refers to horses with excessive muscle glycogen that do not have the *GYS1* mutation. Type 2 PSSM appears to account for about 25% of PSSM seen in Quarter Horse–related breeds and 80% of PSSM seen in Warmblood breeds.⁵⁹ The acronyms EPSM and EPSSM have also been used for polysaccharide storage myopathy, although they do not indicate a specific genotype.⁸⁶

Clinical Signs

Horses with both forms of PSSM often have a calm and sedate demeanor. Clinical signs of muscle stiffness, reluctance to exercise, exercise intolerance, or overt muscle contractures and reluctance to move usually are apparent at the commencement of training.^{46,51} Most horses have numerous episodes of ER or a consistent history of poor performance; however, some mildly affected horses have only one or two episodes of ER per year.⁴⁶ In Quarter Horses, type 1 PSSM has the highest frequency in halter horses, followed by pleasure horses and working cow horses. It is uncommon in racing Quarter Horses. Serum CK activities are often elevated in untreated Quarter Horses, even when horses are rested, and while clinical signs are active, CK will usually increase by 1000 U/L or more 4 hours after 15 minutes of exercise at a trot.⁸⁷ Muscle atrophy, renal failure, and severe colic-like pain are less common presenting complaints. Both type 1 and type 2 PSSM occur in Quarter Horse and Paint horse foals and weanlings without rhabdomyolysis necessarily being induced by exercise (see page 829).

Draft horses with type 1 PSSM show signs of a generalized decrease in muscle mass, overt muscle atrophy, weakness in the hindlimbs with difficulty rising, reluctance to backup, and gait abnormalities.^{54,55,88-90} ER can be a debilitating feature of type 1 PSSM in draft breeds. Although shivers was suggested to be a sign of PSSM, recent studies show there is no causal relationship (see Chapter 48).⁵⁴ Draft horses with PSSM often have only a mild elevation in serum CK and AST. The prevalence of type 1 PSSM is so high in many draft breeds that many homozygous affected horses can be identified.⁹¹ These homozygotes may have more severe clinical signs.

Warmbloods derived from draft crosses may have type 1 PSSM. Many European Warmblood breeds are more

frequently affected by type 2 PSSM.⁵⁹ One of the most common presenting complaints in Warmbloods with PSSM is a gait abnormality characterized by lack of impulsion and shifting undiagnosed lameness.⁵¹ Warmbloods with PSSM also present with sore muscles and ER.

Diagnosis

A diagnosis of type 1 PSSM can be made by testing whole blood or hair root samples for the *GYS1* mutation (<http://www.vdl.umh.edu/vdl/ourservices/neuromuscular.html>). Type 2 PSSM at present must still be diagnosed by muscle biopsy. The distinctive features of type 1 PSSM in muscle biopsy samples are numerous subsarcolemmal vacuoles and dense, crystalline periodic acid–Schiff (PAS)-positive, amylase-resistant inclusions in fast twitch fibers.⁵⁸ A false-negative diagnosis of type 1 PSSM by muscle biopsy may occur if biopsy samples are small or if horses are less than 1 year of age. Muscle biopsies from horses with type 2 PSSM have increased PAS staining for glycogen and aggregates of granular PAS-positive polysaccharide in the cytoplasm or under the sarcolemma.⁹¹ The PAS-positive polysaccharide in type 2 PSSM is frequently, but not always, amylase sensitive. False-positive diagnosis is possible for type 2 PSSM in highly trained horses that normally have higher muscle glycogen concentrations or in formalin-fixed sections that show a greater deposition of subsarcolemmal glycogen in healthy horses. Other features that may be present with both forms of PSSM include muscle necrosis, macrophage infiltration of myofibers, regenerative fibers, and atrophied type 2 fibers.

Etiology

Muscle glycogen concentrations in horses with type 1 PSSM are 1.5 to 4 times normal, and glucose-6-phosphate concentrations are up to 10 times normal.⁹² Increased muscle glycogen concentrations in type 1 PSSM appear to be from increased and unregulated glycogen synthase activity as a result of a gain-of-function mutation in the *GYS1* gene.⁵⁷ Horses with PSSM show increased glycogen synthase activity both in the basal state and when stimulated by glucose-6-phosphate. Elevated insulin in the bloodstream can further enhance glycogen synthase activity. Abnormal amylase-resistant polysaccharide appears to result from production of a polysaccharide with a higher ratio of straight glucose chains, which are created by glycogen synthase, relative to branched chains, which are created by the less active glycogen branching enzyme. Rhabdomyolysis in type 1 PSSM appears to result from a deficiency of energy within individual contracting muscle fibers.⁹³ The genetic defect combined with a high-starch diet appears to produce substrate-limited muscle oxidative metabolism by both impairing production of acetyl coenzyme A from glycogen and by preventing lipolysis and delivery of free fatty acids to skeletal muscle mediated by insulin release. Clinical signs of muscle pain in horses with the *GYS1* mutation may be exacerbated by enhanced individual insulin sensitivity,⁹² as well as by meals that produce elevated blood glucose and insulin levels.⁹⁴ The etiology of type 2 PSSM is not known at present.

Management

Horses with acute rhabdomyolysis can be managed in a fashion similar to that described for sporadic rhabdomyolysis (see page 824).⁸⁷ Episodes of rhabdomyolysis can be

lowered by 75% or more by feeding a diet that is low in starch, supplemented with fat and high in fiber.^{46,94} The primary factor to consider in PSSM horses is their body weight and energy requirements. Overweight horses should begin with a weight-reduction program consisting of grass hay, a ration balancer, a grazing muzzle, and daily exercise following an overnight fast, which elevates plasma free fatty acid levels through lipolysis. Horses with PSSM are much less tolerant of dietary starch and sugar than horses with RER. Horses with a normal body weight should consume diets consisting of good quality grass hay and no high-starch concentrate feed. Instead, a low-starch fat-supplemented feed, such as rice bran-based feeds, complete feeds designed for PSSM, or 250 to 500 mL (1 to 2 cups) of vegetable oil soaked into a low-starch pellet should be provided.^{94,95} Although 1 lb of fat per day has been recommended on some Internet websites, recent research has shown that half as much fat usually works well for many horses with type 1 PSSM.⁹⁴ The amount of digestible energy obtained through starch and sugar should be less than 10% and fat more than 13% per day. Daily exercise is absolutely essential to return PSSM horses to athletic endeavors. As much daily turnout as possible combined with a very gradual training program has a significant impact on decreasing serum CK activity within 30 days.⁹⁴ Box stall rest for more than 12 h/day appears to increase the incidence of rhabdomyolysis in these horses.

Malignant Hyperthermia

Etiology

An autosomal dominant mutation in the skeletal muscle ryanodine receptor (*RYR1*), which is altered in pigs and people with MH, was originally identified in Quarter Horses that developed severe reactions to general anesthesia.⁹⁶ The prevalence of the *RYR1* mutation is in general low; however, within a family of Quarter Horses with type 1 PSSM the prevalence is high.

Clinical Signs

Horses with both the MH mutation and the *GYS1* mutation for PSSM show intermittent but severe signs of muscle pain, stiffness, cramping, and sudden death associated with mild exertion.⁹⁷ Quarter Horses with MH that were masked with halothane and then intubated and maintained on halothane showed a marked increase in body temperature, metabolic acidosis, rigor, and death.⁹⁸

Diagnosis

Genetic testing is recommended in Quarter Horse and Paint horses with a family history of postanesthetic complications or with difficult-to-manage forms of PSSM. Testing is available through the Veterinary Diagnostic Laboratory at the University of Minnesota (<http://www.vdl.umn.edu/vdl/ourservices/neuromuscular.html>).

Treatment

The most successful outcome for a horse with suspected MH would be pretreatment with oral dantrolene (4 mg/kg) 30 to 60 minutes before induction of general anesthesia. There is no cost-effective means to deliver dantrolene to horses intravenously once an episode has begun. Unfortunately, once a fulminant episode is underway it is difficult

to prevent cardiac arrest. Horses with both PSSM and MH respond to a low-starch, high-fat diet and regular daily exercise.⁹⁷

NONEXERTIONAL RHABDOMYOLYSIS

Although exertion is the most common trigger for rhabdomyolysis in horses, many horses can suffer severe rhabdomyolysis without any preceding exertion. Nonexertional rhabdomyolysis may have metabolic, immune-mediated, infectious, nutritional, or toxic causes.

METABOLIC MYOPATHIES

Polysaccharide Storage Myopathy

Clinical Signs

The most common form of PSSM causes the development of muscle necrosis, pain, and firm muscles in adult horses with the onset of training (see section on Polysaccharide Storage Myopathy, page 828). A subset of horses with both type 1 and type 2 PSSM and a concurrent illness may develop rhabdomyolysis without any preceding exercise. Rhabdomyolysis may be so severe that horses become recumbent and unable to rise. Initial muscle swelling and firmness may give way to substantial atrophy after a few days. This form of PSSM was described in weanling and yearling Quarter Horses with concurrent bacterial pneumonia or diarrhea.⁹⁹ In addition to serum CK greater than 200,000 U/L, electrolyte abnormalities such as hyponatremia, hypochloremia, hypocalcemia, hyperphosphatemia, and hyperkalemia are common as a result of the loss of partitioning between extracellular and the large intramuscular fluid compartment and, in some horses, renal compromise.¹⁰⁰ Foals with type 2 PSSM may have a history of a stiff gait and difficulty producing the power required to stand successfully from a recumbent position without assistance. Serum CK activity in these foals may only be moderately elevated, and the primary clinical signs are weakness and pain. Horses with both type 1 PSSM and the mutation for MH (*RYR1*) can develop severe nonexertional rhabdomyolysis and sudden death.

Diagnosis

A diagnosis of type 1 PSSM and MH can be made by genetic testing. A diagnosis of type 2 PSSM is based on identification of abnormal polysaccharide in PAS stains of muscle biopsies (Figure 83-7). A diagnosis may be complicated by the fact that rhabdomyolysis in weanlings with PSSM may precede the later stage of accumulation of abnormal polysaccharide.¹⁰¹ The diagnosis of PSSM in a weanling may be supported by the identification of PSSM in a muscle biopsy from the dam or sire.⁹⁹

There are many other differential diagnoses for acute rhabdomyolysis in foals. Neonatal foals may have modest increases in CK at birth in conjunction with elevated creatinine and a history of placentitis or dystocia.¹⁰² Septicemia could potentially cause an inflammatory reaction in skeletal muscle of neonatal foals. Most commonly, myodegeneration is caused by vitamin E and selenium deficiency with subsequent peroxidation of cell membranes by oxygen free radicals (see page 834).¹⁰³ Young Quarter Horses have developed acute rhabdomyolysis on infection

Fig. 83-7 • Cryostat-cut sections of a semitendinosus biopsy of a horse with polysaccharide storage myopathy stained with periodic acid-Schiff (PAS) and counterstained with hematoxylin. Note the presence of white subsarcolemmal vacuoles in some fibers and the dark PAS-positive granular inclusions representing abnormal polysaccharide in numerous other muscle fibers.

with *Streptococcus equi* (see page 832).¹⁰⁴ Mild elevations in CK also occur in Quarter Horses with glycogen branching enzyme deficiency (GBED).

Treatment

Acute treatment of rhabdomyolysis is similar to that recommended in the Sporadic Rhabdomyolysis section (pages 824 and 825). Special considerations for foals include stall confinement in those showing pronounced stiffness or weakness and assistance to rise and suckle every hour. Nutritional support in the form of mare's milk or foal pellets should be supplied if they do not suckle adequately. Either the mare should be switched to a low-starch high-fat supplement that the foal can share or the mare's grain should be kept inaccessible to the foal. In recumbent foals, in addition to intravenous fluids and nutritional support, a constant rate infusion of detomidine, lidocaine, butorphanol, or ketamine may be useful to control severe pain and struggling. Dantrolene sodium (4 mg/kg, every 4 to 6 hours, PO) may decrease muscle cell necrosis. Assistance to stand every few hours either manually or using a sling is necessary to improve muscle function and circulation. Cautious handwalking for no more than a few minutes at a time is recommended once the foal is stable and strong enough to ambulate. Whenever possible, stall confinement should be limited to less than 48 hours after the episode of rhabdomyolysis and stiffness subside because prolonged stall confinement may result in an increased incidence of rhabdomyolysis episodes as a result of PSSM. Small paddock turnout with limited ability to move around is recommended once stiffness subsides.

Dietary management of weanling foals is similar to that of adults except that foals have a higher protein requirement than adults, especially with regard to lysine. Feeding alfalfa hay rather than grass hay, combined with balanced commercial low-starch high-fat ration, is recommended to meet nutritional needs of weanlings. In some foals, this may provide excessive sugar, and grass hay may be necessary. As much turnout as possible with other horses to encourage daily exercise is recommended for long-term management of foals with PSSM.

The prognosis for weanlings with nonexertional rhabdomyolysis is guarded because of the high likelihood of recurrence.

Glycogen Branching Enzyme Deficiency (GBED)

Clinical Signs

GBED is a fatal autosomal recessive glycogen storage disorder distinct from PSSM in Quarter Horse and Paint foals.^{105,106} A mutation in the glycogen branching enzyme gene (*GBE1*) causes a deficiency in the glycogen branching enzyme (GBE) responsible for producing a normally configured glycogen molecule in numerous tissues.¹⁰⁷ Approximately 8% of Quarter Horses and Paint horses are carriers of the mutation, and 3% of second and third trimester aborted fetuses submitted to two diagnostic laboratories were found to be homozygous for GBED.¹⁰⁸ Pleasure horses and working cow horses have the highest incidence of GBED carriers.¹⁰⁹ Many foals with GBED are undiagnosed because of the similarity of clinical signs with many neonatal diseases and the current lack of awareness of available genetic testing for stillborn foals and aborted fetuses.

Clinical signs appear to be caused by a lack of intracellular glucose stores for normal tissue metabolism. Foals may be aborted, stillborn, weak after birth, or live to up to 18 weeks of age. Death may be sudden when foals are exercised on pasture, associated with weak respiratory muscles, or the result of euthanasia from persistent recumbency. Treatable flexural deformities of all limbs and recurrent hypoglycemia occur in some affected foals. Persistent leukopenia, intermittent hypoglycemia, and moderate elevations in serum CK (1000 to 15,000 U/L), AST, and γ -glutamyl transferase activities are common laboratory findings.

Diagnosis

Routine post mortem examination usually reveals few abnormalities apart from pulmonary edema in some foals and basophilic inclusions in skeletal muscle and cardiac tissues in foals more than 1 month of age. PAS staining of muscle, heart, and sometimes liver shows notable lack of normal PAS staining for glycogen and a variable amount of abnormal PAS-positive globular or crystalline intracellular inclusions. EM and iodine spectra absorption indicated that the polysaccharide is filamentous, with a very minimally branched structure. The most accurate diagnosis of GBED can be obtained through genetic testing of the foal for homozygous status or the dam/sire for heterozygous status. Many stallion owners offer a free repeat breeding to owners that lose foals, and if a diagnosis is not established, the owner will have a 25% chance of having another GBED-affected offspring on repeat breeding. The Veterinary Genetics Laboratory at the University of California, Davis (www.vgl.ucdavis.edu) and Vet Gen in Michigan (www.vetgen.com) are licensed by the University of Minnesota to test for GBED. Mane or tail hairs with roots intact can be submitted. Diagnostic laboratories should be encouraged to screen aborted fetuses for GBED either through PAS staining of cardiac samples or via genetic testing. Testing also should be strongly advised for prepurchase evaluation of broodmares or stallions.

INFLAMMATORY MYOPATHIES

Immune-Mediated Myopathies

Infarctive Hemorrhagic Purpura

Mild elevations in serum CK activity have been observed in conjunction with purpura hemorrhagica in horses. Rarely, some horses vaccinated for, or exposed to, *S. equi* within the past month develop variable edema, extremely high serum CK activity, acute colic, firm swellings within muscle and under the skin, and unilateral lameness.¹¹⁰ Infarctions of skeletal muscle, subcutaneous tissue, and focal areas of the gastrointestinal tract and lungs resulting from a severe vasculopathy are found in these horses. Infarctive purpura is characterized by leukocytosis, hyperfibrinogenemia, and hypoalbuminemia. A diagnosis is often established based on clinical signs of marked pain, inflammatory leukogram, low serum albumin concentration, leukocytoclastic vasculitis in skin and affected tissues, and very high *S. equi* M protein titer. Successful treatment requires early detection, penicillin for 14 days, and prolonged high doses of dexamethasone (0.12 to 0.2 mg/kg) for at least 10 days, followed by tapering doses of prednisolone at an initial dose of 2 mg/kg. Aggressive steroid treatment is required because horses treated with lower doses progress to intestinal infarction and death.

Immune-Mediated Myositis

Immune-mediated polymyositis (IMM) often occurs in Quarter Horses, although other breeds may be affected. Horses are usually either 8 or less or 16 or more years of age.^{111,112} In approximately one third of horses with IMM, a triggering factor appears to have been exposure to *S. equi* or a respiratory disease.¹¹¹

Clinical Signs

The most prominent clinical sign of IMM in Quarter Horses is rapid onset of muscle atrophy, particularly affecting the back and croup muscles, accompanied by stiffness and malaise. Atrophy may progress to involve 50% of the horses' muscle mass within 1 week and may lead to generalized weakness. Focal symmetrical atrophy of cervical muscles has been reported in a pony with IMM.¹¹²

Diagnosis

Hematological abnormalities are usually restricted to mild to moderate elevations in serum CK and AST activity. However, in some horses with chronic myositis, serum muscle enzyme activities are normal. Muscle biopsy of epaxial and gluteal muscles shows lymphocytic vasculitis, anguloid atrophy, myofiber infiltration with lymphocytes, fiber necrosis with macrophage infiltration, and regeneration in acute stages (Figure 83-8). Biopsies of semitendinosus or semimembranosus muscles may show some evidence of atrophy and vasculitis, but substantial inflammatory infiltrates may be absent in these muscles. The extent of the inflammatory infiltrates in epaxial muscles is such that a diagnosis can often be established from several formalin-fixed samples obtained using an 18-gauge disposable biopsy needle.

The lymphocytic infiltrates seen in muscle samples from horses with IMM contain a high CD4/CD8 ratio with no evidence of IgG binding to myofibers.¹¹¹ The reason

Fig. 83-8 • Immune-mediated myositis: Cryostat-cut sections of a biopsy of the longissimus dorsi from a horse with rapid muscle atrophy stained with hematoxylin and eosin. Note the prominent cuffing of the blood vessels with mononuclear cell infiltrates and the lymphocytes surrounding a number of muscle fibers that is characteristic of immune-mediated myopathy in Quarter Horses.

why specific muscle groups are affected in horses with IMM is unclear.

Treatment

Horses with concurrent evidence of streptococcal infection should be treated with antibiotics. It is prudent to avoid intramuscular injections. Administration of corticosteroids appears to immediately improve signs of malaise and inappetence and prevents further progression of muscle atrophy. Recommended dosages are dexamethasone (0.05 mg/kg) for 3 days, followed by prednisolone (1 mg/kg for 7 to 10 days) tapered by 100 mg/week over 1 month. Serum CK activity often normalizes after 7 to 10 days of treatment. Muscle mass will usually gradually recover over 2 to 3 months even without corticosteroid treatment. Recurrence of atrophy in susceptible horses is common and may require reintroduction of corticosteroid therapy.

Infectious Myopathies

Virus-Associated Myositis

Necrosis of skeletal and cardiac muscle may occur in association with viral diseases such as equine influenza and equine infectious anemia. In most situations, viral-induced muscle damage represents a component of systemic multiple organ system involvement. Equine influenza A2 has been found to cause severe rhabdomyolysis, and equine herpesvirus-1 has been reported to induce primary muscle stiffness and clinical signs resembling ER.^{38,45}

Sarcocystosis Myositis

Cysts of the sporozoan parasite *Sarcocystis* are commonly seen in routine histological sections of the heart, esophageal, and skeletal muscle. More than 90% of horses more than 8 years of age have sarcocysts in esophageal muscles, and 6% of healthy horses have one or more nonreactive sarcocysts in gluteal muscle biopsies.⁵² Cysts usually pose no problem, but multisystemic dysfunction occurs with heavy infestations. Horses with heavy infestation show signs of fever, anorexia, stiffness, weight loss, muscle fasciculations, atrophy, and weakness.¹¹³ Diagnosis of

sarcocystosis requires history, clinical signs, laboratory evaluation, and the demonstration of an inflammatory reaction to immature cysts in muscle biopsies. Infection occurs from contamination of feed by infected canine feces. Successful treatment of one horse with sarcocystosis using phenylbutazone, trimethoprim sulfa, and pyrimethamine was reported.¹¹³

***Streptococcus equi* Rhabdomyolysis**

Severe rhabdomyolysis was reported in young Quarter Horses in association with concurrent *Streptococcus equi equi* submandibular lymphadenopathy and/or guttural pouch empyema.¹⁰⁴ Myonecrosis could be from toxic shock resulting from profound nonspecific T-cell stimulation by streptococcal superantigens and the release of high levels of inflammatory cytokines. An alternative explanation may be bacteremia with local multiplication and production of exotoxins or proteases within skeletal muscle. *S. equi* bacteria were identified in affected muscle using immunofluorescent stains for both Lancefield group C carbohydrate and *S. equi* M protein. There is currently no evidence that the *S. equi* involved is an atypical genetic strain of *S. equi*.

Clinical Signs

Horses develop a stiff gait that progresses rapidly to severely painful, firm, swollen, epaxial, and gluteal muscles. Horses often become recumbent, unable to rise, and unrelenting pain may necessitate euthanasia within 24 to 48 hours.

Diagnosis

Hematological abnormalities include mature neutrophilia, hyperfibrinogenemia, and marked elevations in CK (115,000 to 587,000 U/L) and AST (600 to 14,500 U/L) concentrations. Titers to the M protein of *S. equi* are low in affected horses, unless horses are recently vaccinated for strangles. Titers to another protein called *S. equi* myosin binding protein were high in a small number of horses that were tested.¹⁰⁴ At post mortem, large, pale areas of necrotic muscle are evident in hindlimb and lumbar muscles. The histopathological lesions are characterized by severe acute myonecrosis, with a degree of macrophage infiltration. Sublumbar muscles often show the most severe and chronic necrosis as indicated by greater macrophage infiltration of myofibers.

Treatment

A high mortality rate has been reported. Appropriate therapy includes intravenous penicillin therapy combined with an antimicrobial that inhibits protein synthesis, such as rifampin. In addition, flushing infected guttural pouches and draining abscessed lymph nodes will diminish the bacterial load. NSAIDs and possibly high doses of short-acting corticosteroids may assist in diminishing the inflammatory response. Control of unrelenting pain is a major challenge in horses with severe rhabdomyolysis. Constant-rate infusion of lidocaine, detomidine, or ketamine may provide better anxiety and pain relief than periodic injections of tranquilizers. Horses should be placed in a deeply bedded stall and moved from side to side every 4 hours if they are unable to rise. Some horses may benefit from a sling if they will bear weight on their hindlimbs when assisted to stand.

***Anaplasma*-Associated Rhabdomyolysis**

Clinical signs of acute rhabdomyolysis were reported in a horse in conjunction with *Anaplasma phagocytophilia* infection (formerly *Ehrlichia equi*).¹¹⁴ Typical clinical signs of fever, malaise, and limb edema are accompanied by severe muscle stiffness. Hematological findings include anemia, thrombocytopenia, neutropenia, morula visible in granulocytes, and marked elevations in serum CK and AST concentrations. A diagnosis is confirmed by polymerase chain reaction testing of blood for *A. phagocytophilia*. A direct toxic effect of *A. phagocytophilia* on muscle cells is postulated. The horse in this report was successfully treated with supportive care and oxytetracycline.¹¹⁴

***Clostridium* Myositis**

Clostridium septicum, *Clostridium chauvoei*, *Clostridium sporogenes*, and mixed infections cause acute myonecrosis in horses with a high fatality rate. *Clostridium perfringens* type A is another cause of myonecrosis; however, with early and aggressive treatment mortality rates for infection with this bacterium are about 20%.¹¹⁵ There is usually only one primary site of infection that is associated with an injection or deep wound.^{116,117} Clostridial spores may lie dormant in skeletal muscle,¹¹⁸ or direct clostridial spore deposition into the tissue may occur in association with a penetrating injury. If suitable necrotic conditions exist, the spores convert to the vegetative, toxin-producing form of the organism. Powerful exotoxins responsible for the local necrotizing myositis and systemic toxemia are released by proliferating clostridia. Myocardial damage occurs in some horses.

Clinical Signs

Horses often have a history of colic, vaccination, exertional myopathy, penetrating wound, and/or intramuscular injections in the preceding 48 hours. Affected horses usually rapidly develop depression, swelling, and crepitus at the injection site, as well as a fever, toxemia, and tachypnea.¹¹⁶ Crepitus is not always present.¹¹⁵ Tremors, ataxia, dyspnea, recumbency, coma, and death may occur within the next 12 to 24 hours. Hematology and serum biochemical analyses usually reflect a generalized state of debilitation and toxemia (e.g., hemoconcentration and a stress/toxic leukogram may be present). Moderate elevations in the activities of serum CK and serum AST usually occur; however, they often do not reflect the toxicity of clostridial myonecrosis.

Diagnosis

Ultrasonographic evaluation of swollen areas may reveal fluid and characteristic hyperechogenic gas accumulation. A specific diagnosis is best made from aspirates of affected tissues examined via direct smears, fluorescent antibody staining, and anaerobic bacterial culture. Cut tissue from the affected area may reveal abundant serosanguineous fluid with an odor of rancid butter. At post mortem, swelling, crepitus, and autolysis are rapid, and blood-stained fluid is often observed discharging from body orifices.

Treatment

Aggressive antibiotic therapy, wound fenestration, aggressive surgical debridement over the entire affected area, and supportive care are the hallmarks of successful treatment.¹¹⁵

High doses of intravenous potassium penicillin are recommended every 2 to 4 hours until the horse is stable (1 to 5 days), combined or followed by oral metronidazole. Supportive fluid therapy and antiinflammatory agents for control of pain and swelling are recommended. Short-acting corticosteroids such as prednisolone or hydrocortisone may be used for initial therapy of systemic/toxic shock, but continued use is contraindicated in the face of overwhelming infection. Extensive skin sloughing over the affected area is common in surviving horses.

Postinjection Muscle Soreness and Abscessation

Intramuscular injection of a variety of drugs and vaccines may be followed by severe localized muscle soreness, with or without swelling. Injections in the neck may result in neck stiffness and a bilaterally shortened forelimb stride. Injections in the gluteal muscle mass or thigh region can cause unilateral hindlimb stiffness and lameness. These reactions are usually transitory, but occasionally muscle abscessation is a sequel.

A muscle abscess results in localized swelling, heat, and pain. The extent of the abscess, its depth, and the thickness of the walls may be determined ultrasonographically. Surgical drainage or complete abscess excision is required.

Other Muscle Abscesses

Suppurative myositis may arise through penetrating injuries, hematogenous spread of infection, or via local spread of infection. Initially there is an ill-defined cellulitis, which may heal or progress to a well-defined abscess (Figure 83-9). An abscess may heal, expand, or fistulate, usually

Fig. 83-9 • Transverse ultrasonographic image of the lateral aspect of the antebrachium of a pony with cellulitis previously unresponsive to antimicrobial treatment. There was extensive soft tissue swelling throughout the antebrachium and carpal regions, with effusion in the carpal sheath and the tendon sheaths of extensor carpi radialis and the long and lateral digital extensor tendons. The pony was severely lame. There is a localized, partly fluid-filled developing abscess (arrow).

to the skin surface. Once fistulated, the abscess may collapse and heal or result in a chronic granuloma with intermittent discharge. *Staphylococcus aureus*, *S. equi*, and *Corynebacterium pseudotuberculosis* are commonly isolated from skeletal muscle abscessation.

The effect of an abscess on the horse's gait depends on its location and can vary from mild stiffness to severe lameness.

Diagnosis is confirmed by ultrasonography or by culture of aspirated fluid. Abscesses lying deep within muscles can be difficult to diagnose. There may be an elevated fibrinogen level and nucleated white blood cell count. The synergistic hemolysin inhibition test, detecting antibodies to *C. pseudotuberculosis*, can be helpful for detection of internal abscesses.⁹⁹

Treatment consists of poulticing, lancing, flushing, and draining. Occasionally surgical excision may be required for complete removal. The use of antimicrobial drugs is controversial but may be recommended for corynebacterial abscesses. Commonly recommended drugs include procaine penicillin (20,000 U/kg IM twice daily) and crystalline penicillin (20,000 to 40,000 U/kg IV four times daily) alone or in combination with rifampin (5 mg/kg PO twice daily). If antimicrobial therapy is used, it should be continued for several weeks.

Prognosis is usually good for horses with superficial abscesses. Horses with deep abscesses are more difficult to manage successfully. Prolonged resolution or recrudescence often occurs with corynebacterial abscesses.

Traumatic Myopathies

Postanesthetic Myopathy

Postanesthetic myopathy occurs as a unilateral problem, such as triceps myopathy, a bilateral problem, such as hindlimb adductor myopathies, or as a generalized condition.¹⁰² In horses anesthetized in lateral recumbency, the dependent triceps muscle is most commonly affected, whereas the longissimus dorsi and gluteal muscles are usually affected in horses positioned in dorsal recumbency.

Hypoperfusion of muscle groups is the most important causative factor, often the result of increased intracompartmental pressure. Positioning of the horse on the operating table is critical. Compressing muscles against a hard, unyielding surface, venous drainage obstruction, and hypotension may all be contributory factors. Generalized myopathies may occur independent of positioning, and hypotension may play a greater role in these horses. The longer the duration of general anesthesia, the higher the risk.

Clinical Signs

Clinical signs are usually evident as soon as the horse tries to stand but may be delayed for up to 2 hours. Horses with severe myopathy may be unable to stand. Triceps myopathy is often characterized by a dropped elbow stance similar to that seen in horses with radial nerve paralysis. Involvement of the gluteal muscles may result in unwillingness to bear weight on the hindlimbs. Horses may appear distressed, with profuse sweating, tachycardia, and tachypnea. The degree of distress depends on the severity of the muscle damage. Affected muscles may feel very firm to near hard. There may be localized swelling.

Diagnosis

Diagnosis is confirmed by measurement of serum CK concentration. The concentration is often increased after general anesthesia, but levels greater than 2000 U/L indicate the presence of myositis. The CK concentration may be normal immediately after the horse stands, but as blood flow returns to the affected muscles, the concentration will increase and peak 4 hours after initiation of the event.

Treatment and Prognosis

Treatment aims to relieve distress and pain, to encourage perfusion of muscles, and to keep the horse standing if at all possible. Pain relief is provided by NSAIDs, such as phenylbutazone (4.4 mg/kg) or flunixin meglumine (1 mg/kg), combined with opiate analgesics (e.g., butorphanol, 0.1 mg/kg) if necessary. Sedation with detomidine in horses with severe pain or acepromazine (0.05 mg/kg) in those with mild pain may be required. Constant-rate infusions of detomidine or butorphanol may be beneficial for pain control. Fluid therapy is important to maintain renal perfusion and urine output and to ensure adequate muscle perfusion. A balanced polyionic electrolyte solution should be infused at up to 20 mL/kg/h for the first several hours.

The prognosis for horses with unilateral myopathy is usually good, although with severe damage there may be residual muscle fibrosis, which may compromise function. With persistent clinical signs, ultrasonographic examination may be useful to determine the extent and severity of muscle damage.¹¹⁹ The prognosis for generalized myopathy is more guarded.

Prevention

Prevention requires careful preoperative planning to minimize the time under general anesthesia, careful positioning of the horse on the operating table, and maintenance of arterial blood pressure greater than 60 mm Hg using fluid therapy and inotropic agents such as dobutamine (1 to 5 mcg/kg/min). The position of the horse on the operating table is in part dictated by the surgical procedure. With horses in lateral recumbency, the dependent forelimb should be pulled forward, and the upper limb should be supported at least parallel to the table. The hindlimbs should be supported parallel to, or above parallel, and adequately separated to permit venous drainage. With horses in dorsal recumbency, support of the forelimbs or hindlimbs in a semiflexed position using an overhead hoist or side bars can be helpful.

Gastrocnemius Muscle Injury

Gastrocnemius muscle injury in foals and adult horses is discussed in Chapter 80.

Fibrotic Myopathy

Fibrotic myopathy is discussed in Chapters 47 and 48.

Compartment-like Syndrome in the Antebrachium

Compartment syndrome is a condition in which high pressure within a closed fascial space reduces capillary blood perfusion below a level necessary for tissue viability. The syndrome develops in skeletal muscle enclosed by relatively noncompliant osseofascial boundaries.¹²² Elevated intracompartmental pressure may result from increased intracompartmental fluid or from decreased compartment

size. Increased pressure from fluid accumulation may be the result of muscle trauma and hemorrhage or a sequel to prolonged ischemia and subsequent reperfusion and edema. Prolonged elevated pressure greater than 30 mm Hg resulted in myonecrosis in the dog.¹²³

A compartment-like syndrome was described in the horse involving the caudolateral muscle compartment of the antebrachium.¹²⁴ This encloses the lateral digital extensor, ulnaris lateralis, superficial and deep digital flexor and flexor carpi ulnaris muscles, and also the median artery, vein, and nerve.

Lameness is a sequel to trauma and is acute and severe in onset, with reluctance to bear weight on the limb associated with firm swelling on the caudolateral aspect of the antebrachium. Digital pulse amplitudes in the more distal part of the limb may be reduced if the limb is flexed or extended. With time, the affected muscle mass may become cold.

Treatment is by fasciotomy. Incising the superficial fascia over ulnaris lateralis resulted in immediate separation of the fascia by 3 to 4 cm and rapid relief of clinical signs.¹²⁴

▣ NUTRITIONAL MYOPATHIES

John Maas and Stephanie J. Valberg

NUTRITIONAL MYODEGENERATION

Etiology

Nutritional myodegeneration (NMD) (white muscle disease, nutritional muscular dystrophy) is an acute degenerative disease of cardiac and skeletal muscle caused by a dietary deficiency of selenium and/or vitamin E.^{103,125} Marginally to severely selenium-deficient areas occur in regions of numerous countries throughout the world.^{125,126} This syndrome occurs in young, rapidly growing foals born to dams that consumed selenium-deficient diets during gestation. The disease has also been implicated in masseter muscle myopathy and occasionally nonexertional rhabdomyolysis in adult horses. Selenium and vitamin E appear to be synergistic in preventing NMD. However, based on prophylaxis and response to treatment, selenium deficiency appears to be the most important contributor.

Clinical Signs

Foals with primary necrosis of myocardium and respiratory muscles have dyspnea, a rapid irregular heartbeat, profound weakness, recumbency, and sudden death.^{100,103} The skeletal muscle form of NMD frequently has a slower onset of muscular weakness, trembling, stiffness, or inability to stand. Most affected foals are able to stand only for short periods. Supporting muscle groups may appear swollen and may be hard and painful on palpation. Commonly affected muscle groups include the gastrocnemius, semitendinosus, semimembranosus, and biceps femoris and muscles of the lumbar, gluteal, and neck regions. If the diaphragm and intercostal muscles are affected, the foal may show respiratory distress and evidence of increased abdominal effort when breathing. Myocardial damage and signs consistent with cardiac dysfunction may be apparent. Dysphagia from necrosis in the tongue may be the only sign in some affected foals and is frequently accompanied by aspiration pneumonia. Foals with primary muscular NMD often show

improvement after a few days of rest and treatment with selenium and can often stand and walk within 3 to 5 days. In the western United States, selenium-responsive NMD is seen in adult horses that were extremely deficient in selenium during the winter (snow on the ground), and the only clinical signs have been myoglobinuria (red snow) and mild stiffness in the morning.

Clinical Pathology

Substantially elevated serum CK concentration in the thousands to hundreds of thousands of units per liter along with high AST and LDH activities occur during myodegeneration. Progressively decreasing CK activity can be used as a prognostic indicator of cessation of myodegeneration. Hyperkalemia, hyperphosphatemia, hyponatremia, hypochloremia, and hypocalcemia can occur with severe rhabdomyolysis when the normal distinction between extracellular and intracellular compartments is destroyed by massive tissue necrosis.¹⁰⁰ Myoglobinuria is common. Elevated serum protein concentrations and hemoconcentration commonly reflect dehydration in foals unable to nurse or drink water, as well as fluid shifts into damaged tissues. Neutrophilia is common because of the high incidence of aspiration pneumonia.

Diagnosis

Whole blood selenium and plasma vitamin E samples can be used to assess intermediate to long-term nutritional status. Whole blood selenium analysis is preferred over plasma and serum.¹²⁷ Whole blood selenium concentrations ranging from 0.07 to more than 0.1 ppm are considered normal. Short-term oral or intramuscular supplementation of selenium can confuse interpretation of circulating selenium concentration. Selenium-dependent glutathione peroxidase (GSH-Px) formed in the red cells during erythropoiesis also provides an index of body selenium status. Adequate GSH-Px activities are greater than 20 to 50 U/mg of hemoglobin/min in horses. However, GSH-Px reference values are only specific to the laboratory where the analysis is performed and must be validated by comparison with blood selenium concentration. The activity of GSH-Px in red blood cells of domestic species remains constant for 4 to 6 days when maintained at 39° F (4° C); after this time, significant decreases occur. The critical concentration of vitamin E (α -tocopherol) in plasma is 1.1 to 2 ppm. Vitamin E deteriorates rapidly in plasma samples. Therefore plasma samples for α -tocopherol analysis need to be put on ice immediately, protected from the light by wrapping in tin foil, and stored frozen (−21° F, −70° C) if analysis is to be delayed.

Pathology

Bilaterally symmetrical myodegeneration is a consistent finding in NMD.¹⁰³ Skeletal muscle degeneration is characterized by pale discoloration and a dry appearance of affected muscle, white streaks in muscle bundles, calcification, and intramuscular edema. The white streaks seen in muscle bundles represent bands of coagulation necrosis or, in horses with chronic disease where insults may have occurred weeks before, may represent fibrosis and calcification. Affected muscle bundles are often adjacent to apparently normal or minimally affected muscle. Histologically, affected muscle fibers may be hypercontracted and

fragmented, with some mineralization of muscle fibers and macrophage infiltration.¹²⁸ Tissue biopsies and tissue specimens obtained at necropsy can be assayed for selenium content. Normal liver concentrations of selenium are 1.05 to 3.5 ppm on a dry matter (DM) basis. Fresh liver is approximately 30% DM in adult horses.

Pathophysiology

During normal cellular metabolism, highly reactive forms of oxygen (free radicals) are produced. These include hydrogen peroxide, hydroperoxides, lipoperoxides, superoxide, various hydroxy radicals, and singlet oxygen. Vitamin E is active within the cell membrane as a lipid-soluble antioxidant that scavenges free radicals that otherwise might react with unsaturated fatty acids to form lipid hydroperoxides. In contrast, GSH-Px destroys hydrogen peroxide and lipoperoxides that have already been formed and converts them to water or relatively harmless alcohols. Other enzymes such as catalase and superoxide dismutase are also involved in this protective process. It is believed that a deficiency of selenium results in rhabdomyolysis through oxidant damage to muscle cell membranes. The precise interrelationships between selenium, vitamin E, other metabolic factors, and triggering mechanisms in NMD are not fully understood because many horses deficient in selenium and/or vitamin E have no evidence of muscle disease. In certain situations, deficiencies of both selenium and vitamin E are necessary for disease to occur. In other horses, NMD can occur when a deficiency of only one of the nutrients is present and the other is normal in blood and tissues.

Treatment and Prognosis

Myocardial damage is often extensive and incompatible with life with the cardiac form of NMD. Only rarely is treatment successful. In contrast, the skeletal form of NMD is more generally amenable to treatment, although the prognosis for clinical recovery from the skeletal form of NMD is guarded and depends often on whether secondary complications such as respiratory disease develop. In all horses with NMD, therapy should involve specific supplementation with selenium and vitamin E and general supportive care.

Alleviation of selenium-responsive NMD requires the use of injectable selenium products. These are available with selenium concentrations varying from 1 mg/mL of selenium to 5 mg/mL, with all products containing 50 mg/mL (68 U) of vitamin E as DL- α -tocopherol acetate. The label dose for selenium is 0.055 to 0.067 mg/kg (2.5 to 3 mg/45 kg) body weight given intramuscularly or subcutaneously. Dosage of these injectable products should not be greatly increased above the label dose to prevent an inadvertent selenium toxicosis. Absorption and distribution of injectable selenium occur rapidly and may account for the rapid improvement in clinical signs seen in reversible cases.

The amount of vitamin E in vitamin E/selenium combinations is insufficient for vitamin E supplementation. Injectable vitamin E products are now available that contain 300 U vitamin E/mL as D- α -tocopherol (Vital E, Schering-Plough Animal Health, Boxmeer, The Netherlands). Administration of these products increases the tissue and/or plasma level of vitamin E activity for approximately 3 weeks. The bioavailability of vitamin E from injectable

products depends on the form of vitamin E (the alcohol form, D- α -tocopherol, being the most active) and the amount and quality of the solution emulsifier used. Oral vitamin E supplementation is a good approach to supplement dietary levels with natural vitamin E providing the highest bioavailability. Daily recommended levels of supplementation for horses range from 600 to 1800 mg of DL- α -tocopheryl acetate.¹²⁹ Oral α -tocopherol is now available for all species and contains 500 U vitamin E/mL (Emcelle, Stuart Products, Inc., Bedford, Texas, United States). The recommended dosage of this product is 0.5 to 1.5 U/kg body weight.

Supportive therapy may include administration of antibiotics to help combat secondary pneumonia and infected decubital lesions that are common in recumbent horses. If dysphagic, horses should be fed via nasogastric tube, and provision of adequate energy intake and attention to the fluid and electrolyte balance are of critical importance if recovery is to be successful. Hyperkalemia may be life threatening in affected foals. Mineralocorticoids, alkalinizing fluids, and dextrose and insulin may be used to reduce circulating potassium concentrations.¹⁰⁰

Prevention and Control

NMD is prevented and controlled through supplementation of selenium and vitamin E. Oral supplementation for horses at 1 mg/day of selenium increases blood selenium concentrations above levels known to be associated with NMD.^{130,131} Supplementation of pregnant mares is advised in areas known to be selenium deficient; however, only limited selenium may cross the placenta.¹⁰⁷ Supplementation during lactation increases the levels of selenium in milk and thus provides a potential means of selenium supplementation in foals; however, evidence in cattle indicates that this increased level of selenium in milk may not meet the foal's nutrient requirements.¹³² Supplementation of selenium by use of injectable selenium products alone would require treatment every 30 to 45 days and would provide only partial amounts of the recommended level of selenium.¹³³

Regardless of the method of supplementation, periodic blood (or tissue) sampling of horses at risk is necessary to ensure maintenance of desired levels of selenium. In high-risk areas, samples should be taken every 60 to 90 days to determine selenium status in susceptible horses and every 6 to 12 months to monitor supplementation. Based on these assessments, adjustments to the rate or extent of selenium supplementation may be made. Feeding horses properly prepared and stored hay and grain or allowing them access to high-quality green forage should ensure adequate vitamin E intake.

TOXIC MYOPATHIES

Ingestion of a number of toxic substances in feed or forage may cause rhabdomyolysis in horses.

Ionophores

Ionophores are commonly added to ruminant feeds to promote growth and to control coccidia. However, horses are 10 times more sensitive to the toxic effects of ionophores in feed than cattle. When equine feeds are

inadvertently contaminated with ionophores or horses eat cattle feed, cardiomyopathy is the most common chronic sequela, although some horses may die acutely with colic-like signs, myoglobinuria, hypokalemia, cardiac arrhythmia, and tachypnea.¹³⁴

Pasture Myopathies

Tremetone

Horses ingesting 0.5% to 2% body weight of tremetone-containing plants are likely to die from skeletal muscle and cardiac muscle necrosis. Horses show marked depression, weakness, low head posture, and increased cardiac and respiratory rate. Serum AST and CK concentrations are often markedly elevated, and serum electrolyte abnormalities such as hypocalcemia, hyponatremia, hypochloremia, hyperkalemia, and hyperphosphatemia may be present. Treatment is generally supportive as described in the section on acute ER. Tremetone was identified in white snakeroot (*Eupatorium rugosum*) and rayless goldenrod (*Isocoma wrightii*). White snakeroot grows in shaded areas of the eastern and central United States.¹³⁵⁻¹³⁷ Rayless goldenrod is common in the southwestern United States on open pastures. Tremetone remains active in the hay and in the stalks of the dead plants on pasture, so both the fresh and the dried form of the plants should be kept from horses.¹³⁶

Cassia occidentalis

Muscle necrosis may also occur in horses ingesting *Cassia occidentalis* seeds prevalent in the southeastern United States.¹³⁸ Horses develop incoordination, recumbency, and death. Gross skeletal muscle lesions are not present, but histopathological lesions include segmental myonecrosis.

Blister Beetles

One of 70 horses poisoned with blister beetles developed muscle necrosis.¹³⁹

Atypical Myoglobinuria

Atypical myoglobinuria occurs sporadically in horses kept at pasture, usually with no supplemental feeding.^{140,141} It has been recognized most commonly in the United Kingdom and Europe, but a similar syndrome has been seen in the midwestern United States.¹⁴² The cause is unknown but appears to involve disruption in lipid metabolism from exposure to a toxin in well-grazed, cool wet pastures.^{143,144} It occurs most often in spring and autumn and is often associated with a sudden deterioration in weather conditions.^{141,145} The clinical signs are sudden in onset and rapidly progressive, frequently resulting in death. Several horses in a group may be affected, although some may remain without symptoms. Affected horses are reluctant to move, have muscle weakness, fasciculations, and may become recumbent. Choke may be present, and gut sounds may be reduced, with a reduction in fecal production, although appetite may be unaffected. Heart rates may be markedly elevated, and pulmonary edema may be present. The horses do not show signs of pain, despite post mortem evidence of widespread myopathy. Metabolic and respiratory acidosis, elevated cardiac troponin I concentration, substantial increases in serum CK and AST levels, and myoglobinuria are common.

Post mortem examination reveals widespread myodegeneration in skeletal muscles and the myocardium. Special stains for lipid reveal excessive lipid storage in the heart, diaphragm, and other oxidative postural muscles.^{142,143} Multiple chain lengths of acylcarnitines are elevated in urine or plasma.¹⁴⁴ Supportive therapy including antioxidants such as vitamin C, vitamin E, riboflavin, and intravenous fluids containing dextrose is recommended. Mortality is high in affected horses.

Disorders Associated with Muscle Fasciculations or Myotonia

A variety of muscle disorders exist in the horse that can cause muscle fasciculations, muscle cramping, and, in some, recumbency. These include metabolic alkalosis combined with hypocalcemia, hypomagnesemia, infestation with ear ticks, myotonia congenita and dystrophic myotonia, and hyperkalemic periodic paralysis. With the exception of ear ticks, these disorders are not associated with a marked elevation in serum CK activity.

Hypocalcemia in Horses

Hypocalcemia (lactation tetany, transport tetany, idiopathic hypocalcemia, and eclampsia) is a relatively rare disorder in horses. Clinical signs of increased muscle tone may resemble tetanus. Horses may show a stiff, stilted gait, rear limb ataxia, muscle fasciculations (especially temporal, masseter, and triceps muscles), trismus, dysphagia, salivation, anxiety, profuse sweating, tachycardia, elevated body temperature, cardiac dysrhythmias, synchronous diaphragmatic flutter, convulsions, coma, and death.¹⁴⁶ Clinical signs of excitability are usually seen when serum calcium values are less than normal but more than 8 mg/dL. Values of 5 to 8 mg/dL usually produce tetanic spasms and incoordination. Concentrations less than 5 mg/dL usually result in recumbency and stupor. This disorder often progresses and may cause death within 48 hours, particularly in lactating mares. A metabolic alkalosis, hypomagnesemia/hypomagnesemia, and hyperphosphatemia/hypophosphatemia have all been found in association with hypocalcemia in horses.^{147,148}

Treatment involves the intravenous administration of calcium solutions such as 20% calcium borogluconate or those recommended for the treatment of parturient paresis in cattle. Administration of these solutions at the rate of 250 to 500 mL/500 kg diluted 1:4 with saline or dextrose will often result in full recovery, although in some horses it may take several days.¹⁴⁶ Relapses do occur. If no response to an initial infusion occurs, a second dose may be given 15 to 30 minutes later. Cardiac rate and rhythm should be closely monitored when calcium-containing solutions are infused intravenously.

Ear Tick–Associated Muscle Cramping

Intermittent painful muscle cramps not associated with exercise were described in horses with severe *Otobius megnini* infestations.¹ These horses show intermittent signs of severe muscle cramping of pectoral, triceps, abdominal, or semitendinosus/semimembranosus muscles lasting from minutes to a few hours, with severe pain that often resembles colic. Horses may fall over when stimulated. Between muscle cramps, horses appear to be normal. Percussion of triceps, pectoral, or semitendinosus muscles results in a

typical myotonic cramp. Horses have serum CK activities ranging from 4000 to 170,000 U/L. Numerous ear ticks, *O. megnini*, can be identified in the external ear canal of affected horses. Without treatment for ear ticks, the spasms continue; however, local treatment of the ear ticks using pyrethrins and piperonyl butoxide results in recovery within 12 to 36 hours later. Acepromazine is helpful to relieve painful cramping.

Myotonia

Myotonic muscle disorders represent a heterogeneous group of clinically similar diseases that share the feature of delayed relaxation of muscle after mechanical stimulation or voluntary contraction. Skeletal muscle ion channel dysfunction producing abnormal muscle membrane excitability or abnormalities in mRNA processing^{149,150} appear to be the shared abnormality among myotonias in many species.

Clinical Signs

Foals with myotonia congenita usually have conspicuously well-developed musculature and mild hindlimb stiffness.^{151–153} Gait abnormalities are usually most pronounced when exercise begins and frequently diminish as exercise continues. Bilateral bulging (dimpling) of the thigh and rump muscles is often obvious and exacerbated by stimulation of affected muscles by percussion. Affected muscles may remain contracted for up to 1 minute or more with subsequent slow relaxation. A variety of breeds of horses have been described with this disorder, but an inherited basis for myotonia has not been established.

A more severe progressive form of myotonia that eventually results in debilitating muscle atrophy, fibrosis, and stiffness has been observed in Quarter Horse foals.^{154–157} At birth, foals with myotonia dystrophica appear well-muscled, and slight stiffness disappears with exercise. As the condition progresses, muscle hypertrophy is less obvious, atrophy may occur, and exercise may produce debilitating muscle contractures. Foals may become so stiff they are unable to stand. This condition resembles myotonia dystrophica in people in that numerous organ systems may be involved. Retinal dysplasia, lenticular opacities, and gonadal hypoplasia have been reported in one such Quarter Horse foal.¹⁵⁵

Diagnosis

A diagnosis of both forms of myotonia is best made by EMG. High-frequency crescendo-decrescendo action potentials with a classic “dive-bomber” pattern are characteristic for myotonia. Muscle biopsies may be normal or show fiber hypertrophy and an increased proportion of type 1 fibers with myotonia congenita. Muscle biopsies from horses with myotonia dystrophica show fiber-type grouping, increased numbers of cells with centrally located nuclei, sarcoplasmic bodies, ring fibers, and fibrosis.^{154,156}

Treatment

Foals with myotonia congenita do not usually demonstrate progression of clinical signs beyond 6 to 12 months of age. Phenytoin may diminish clinical signs, but no long-term treatment is available.⁸³ The prognosis for foals with myotonia dystrophica is extremely poor, and most foals are euthanized by 1 year of age.

Stiff-Horse Syndrome

A condition called stiff-horse syndrome has been described in Belgium and is characterized by stiffness and muscle spasms, associated with an abnormally straddled posture.¹⁵⁸ The muscle spasms were typically triggered by voluntary movements, such as going to eat from the manger or being led from the stable. EMG showed persistent motor unit activity in the axial and gluteal muscles. The clinical signs were responsive to oral prednisolone therapy but recurred after treatment stopped. Several similar cases have been seen in the United Kingdom.^{159,160} The etiology of the condition is currently unknown. Similar conditions have been recognized in people, some of which are thought to be autoimmune.

Muscle Fasciculation of Unknown Cause

One horse had a history of sudden onset severe hyperesthesia and intense muscle fasciculations of the longissimus dorsi muscles in the thoracolumbar region, stimulated by light touch.¹⁵⁹ No underlying cause was identified. It was speculated that pain may be neuropathic in origin, and the horse responded to treatment with gabapentin (4 mg/kg PO BID), with complete resolution of clinical signs.

Muscle Fasciculation Associated with Osteoarthritis of the Caudal Cervical Synovial Articulations

Several horses have shown an episodic transient forelimb lameness, unresponsive to local analgesic techniques in association with ipsilateral or bilateral fasciculation of the pectoral and shoulder muscles after exercise, and neck stiffness.¹⁵⁹ All have had massive enlargement of the synovial articulations between the sixth and seventh cervical vertebrae, with ventral buttressing. Episodic nerve root impingement is thought to be the underlying cause of the muscle fasciculation and lameness. Intraarticular medication with corticosteroids has resulted in short term (months) resolution of clinical signs.

■ HYPERKALEMIC PERIODIC PARALYSIS

Sharon J. Spier

Hyperkalemic periodic paralysis (HyPP) is an autosomal dominant trait affecting Quarter Horses, American Paint horses, Appaloosas, and Quarter Horse crossbreeds worldwide.¹⁶¹⁻¹⁶³ The genetic disease has been linked to a prolific Quarter Horse sire named Impressive. Current estimates indicate that 4% of the Quarter Horse breed may be affected.^{162,164,165} Affected horses may have been preferentially selected as breeding stock for pronounced muscle development, and there is evidence of selection of HyPP-affected horses as superior halter horses by show judges.¹⁶⁴

Clinical Signs

Clinical signs among horses carrying the same mutation range from asymptomatic to daily muscle fasciculations and weakness. In the majority of horses, intermittent clinical signs begin by 2 to 3 years of age, with no apparent abnormalities between episodes. Ingestion of diets high in potassium (>1.1%), such as those containing alfalfa hay, molasses, electrolyte supplements, and kelp-based

supplements, or sudden dietary changes commonly trigger episodes.^{161,162,166-168} Fasting, general anesthesia or heavy sedation, trailer rides, and stress may also precipitate clinical signs; however, the onset of signs is often unpredictable without a definable cause. Other possible precipitating factors that have been noted in people and horses are exposure to cold, fasting, pregnancy, and concurrent disease and rest following exercise. Exercise per se does not appear to stimulate clinical signs, and serum CK shows no change to very modest increases during episodic fasciculations and weakness.

In most horses, clinical episodes begin with a brief period of myotonia, with some horses showing prolapse of the third eyelid. Sweating and muscular fasciculations are observed commonly in the flanks, neck, and shoulders. The muscle fasciculations become more generalized as additional muscle groups are involved. Stimulation and attempts to move may exacerbate muscular fasciculations. Some horses may develop severe muscle cramping. Muscular weakness during episodes is a common characteristic of HyPP. Horses remain standing during mild attacks. In more severe attacks, clinical signs may progress to apparent weakness with swaying, staggering, dog sitting, or recumbency within a few minutes. Heart and respiratory rates may be elevated, and horses may show manifestations of stress yet remain relatively bright and alert during episodes. Affected horses usually respond adversely to noise and painful stimuli during attacks. Episodes last for variable periods, usually from 15 to 60 minutes. Several horses have died during acute episodes. Respiratory distress occurs in some horses as a result of paralysis of upper respiratory muscles, and a tracheostomy may be necessary. In addition, young horses that are homozygous for the HyPP trait have been observed to manifest a respiratory stridor and periodically may develop obstruction of the upper respiratory tract.^{169,170} Horses homozygous for HyPP may have dysphagia or respiratory distress, and endoscopic findings include pharyngeal collapse and edema, laryngopalatal dislocation, and laryngeal paralysis. Once the episode subsides, horses appear normal with no apparent or minimal gait abnormalities. Although HyPP horses appear normal between attacks, examination using EMG reveals abnormal fibrillation potentials, complex repetitive discharges with occasional myotonic potentials, and trains of doublets between episodes.^{162,171}

Etiology

HyPP is caused by a point mutation that results in a phenylalanine/leucine substitution in a key part of the voltage-dependent skeletal muscle sodium channel α -subunit.¹⁶³ In horses with HyPP, the resting membrane potential is closer to firing than in normal horses. Sodium channels are normally briefly activated during the initial phase of the muscle action potential. The HyPP mutation results in a failure of a subpopulation of sodium channels to inactivate when serum potassium concentrations are increased. As a result, an excessive inward flux of sodium and outward flux of potassium ensues, resulting in persistent depolarization of muscle cells and temporary weakness.

Diagnosis

In most affected horses, hyperkalemia (6 to 9 mEq/L), hemoconcentration, and hyponatremia occur during

episodes, but acid-base balance is normal.^{161,162} Serum potassium concentrations return to normal following cessation of clinical signs. Some affected horses may have normal serum potassium concentrations during minor episodes of muscle fasciculations. Differential diagnoses for hyperkalemia include delay before serum centrifugation, hemolysis, acidosis, renal failure, severe rhabdomyolysis, and high-intensity exercise.

Because veterinarians may not be present during acute episodes, the definitive test for identifying HyPP is the demonstration of the base-pair sequence substitution in the abnormal segment of the DNA encoding for the α -subunit of the sodium channel. Submission of mane or tail hair should be made to appropriate genetic laboratories.

Descent from the stallion Impressive on the sire's or dam's side in a horse with episodic muscle tremors is strongly suggestive of HyPP. To increase public awareness of this genetic defect, mandatory testing for HyPP with results designated on the Registration Certificate began for foals descending from Impressive born after January 1, 1998. In response to requests from the membership, in 2004 the American Quarter Horse Association Stud Book and Registration Committee ruled that foals born in 2007 and later testing homozygously affected for HyPP (H/H) will not be eligible for registration.

Treatment

Low-grade exercise can sometimes abort a mild episode, or if horses are just beginning to exhibit clinical signs. Feeding grain or corn syrup to stimulate insulin-mediated movement of potassium across cell membranes may also be helpful. Other treatment options that may abort an episode include intramuscular administration of epinephrine (3 mL of 1:1000/500 kg) and administration of acetazolamide (3 mg/kg PO every 8 to 12 hours). Many horses experience spontaneous recovery from episodes of paralysis and appear normal by the time a veterinarian arrives.

During severe episodes, administration of calcium gluconate (0.2 to 0.4 mL/kg of a 23% solution diluted in 1 L of 5% dextrose) will often provide immediate improvement. An increase in extracellular calcium concentration raises the muscle membrane threshold potential, which decreases membrane hyperexcitability. To reduce the serum potassium, intravenous dextrose (6 mL/kg of a 5% solution) alone or combined with sodium bicarbonate (1 to 2 mEq/kg) can be used to enhance intracellular

movement of potassium. With severe respiratory obstruction, a tracheostomy may be necessary.

Control

Decreasing dietary potassium and increasing renal losses of potassium are the primary steps taken to prevent HyPP episodes.^{167,168} Avoid feeding high-potassium feeds such as many electrolyte and kelp supplements, alfalfa hay, canary grass hay, orchard grass hay, brome hay, soybean meal, and molasses. Optimally, later cuts of timothy or Bermuda grass hay; grains such as oats, corn, wheat, and barley; and beet pulp should be fed in small meals several times a day. Regular exercise and/or frequent access to a large paddock or yard are also beneficial. Pasture works well for horses with HyPP because the high water content of pasture grass makes it unlikely that horses will consume large amounts of potassium in a short period. Ideally, horses with recurrent episodes of HyPP should be fed a diet containing between 0.6% and 1.1% total potassium concentration. Because there is a wide variation in potassium concentration of forages depending on maturity and soils, it is advisable to have feeds analyzed for potassium concentrations and other nutrient requirements. Commercially available complete feeds with a guaranteed K⁺ content may be more convenient for some HyPP horses, especially for owners with few horses.

For horses with recurrent episodes of muscle fasciculations even with dietary alterations, acetazolamide (2 to 4 mg/kg PO every 8 to 12 hours) or hydrochlorothiazide (0.5 to 1 mg/kg PO every 12 hours) may be helpful. These agents work through different mechanisms; however, both cause increased renal potassium ATPase activity. In addition, acetazolamide stabilizes blood glucose and potassium by stimulating insulin secretion. Breed registries and other associations may have restrictions on the use of these drugs during competitions because diuretics mask prohibited substances.

Prognosis

In most horses, HyPP is a manageable disorder, although recurrent episodes may occur and severe episodes may be fatal. Owners of affected horses should be strongly discouraged from breeding these horses for the long-term health of the Quarter Horse and other breeds. Breeding of an affected horse to a normal horse has a 50% chance of producing a foal with HyPP. Owners of affected horses should advise veterinarians of HyPP status before general anesthesia or procedures requiring heavy sedation.

Therapeutics

SECTION 1

Traditional Therapy

Chapter 84

Principles and Practices of Joint Disease Treatment

C. Wayne McIlwraith

The joint is an organ, and there are a number of ways in which traumatic damage occurs to it, ultimately resulting in degradation of articular cartilage. In 1966, the concurrent damage to joint capsule and ligament attachments that accompanied osteochondral fragmentation and cartilage damage was described.¹ However, the fact that synovitis and capsulitis could cause degradation of articular cartilage was not known until later. Experimentally, cartilage morphological damage and loss of glycosaminoglycan (GAG) staining occurred in the absence of instability or traumatic disruption of joint soft tissues.² Surveys estimate that approximately 60% of lameness is related to osteoarthritis (OA).^{3,4} Rapid resolution of synovitis and capsulitis is critical in management of OA because synovitis induces cartilage matrix degradation. The goals of treatment of traumatic joint injuries are twofold: to return the joint to normal as quickly as possible and to prevent occurrence or to reduce the severity of OA, thus to minimize lameness and joint deterioration. Medical management is largely used to minimize OA, but timely surgery to remove osteochondral fragments, to reduce and repair large intra-articular fractures in an appropriate fashion, to diagnose accurately ligamentous and meniscal injuries using arthroscopy, and to manage manifestations of osteochondrosis can be critical to prevent OA. This chapter addresses both medical and surgical management.

MEDICAL TREATMENT

The goal to manage acute synovitis, with or without capsulitis, is to return the joint to normal as quickly as possible. In addition to reducing lameness and returning the horse to work, suppression of synovitis and capsulitis is important to prevent the byproducts of inflammation from

compromising articular cartilage and causing OA. Pain relief and minimizing the potential microinstability associated with excessive synovial effusion are both also critical. As information increases regarding potential targets for therapeutic intervention, the range of treatment options has increased. Medications that provide pain relief, but for which any therapeutic action at the level of cartilage matrix has not been defined, are termed symptom-modifying osteoarthritic drugs (SMOADS). Disease-modifying osteoarthritic drugs (DMOADs) are those agents that can positively influence either the articular cartilage or the synovial environment. DMOADs were previously called chondroprotective drugs.

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) are antiinflammatory agents that inhibit some components of the enzyme system that converts arachidonic acid into prostaglandins and thromboxane. Prostaglandin (PG) E₂ (PGE₂) is the product associated with synovial inflammation and cartilage matrix depletion and was demonstrated in the synovial fluid of horses with OA.^{5,6} Phenylbutazone is the most commonly used NSAID in the horse, given at a dose of 2.2 mg/kg, once or twice daily. However, results are variable both in horses with naturally occurring OA⁷ and in experimental trials using an equine OA model developed at Colorado State University (CSU), which has been used to assess a number of commonly used medications.⁸ Lameness scores were lowest after administration of the combination of phenylbutazone with flunixin meglumine compared with phenylbutazone alone, but concerns with secondary side effects (including acute necrotizing colitis) were raised.⁸

All NSAIDs inhibit cyclooxygenase (COX) activity to some degree,^{5,6} but more recently two different isoenzymes called COX-1 and COX-2 were reported with potential importance in the horse. COX-1 maintains the “good” or “housekeeping” portion (constitutive part) of the COX pathway.⁹ COX-1 is important in the balance of normal physiology of the gastrointestinal and renal systems but plays a lesser role in the inflammatory COX cascade. COX-2 is associated with inflammatory events, especially those driven by macrophages and synovial cells, plays a minor role in normal physiology, and is considered the “bad” or “inducible” portion of the COX pathway. Drugs that preferentially inhibit COX-2 have been developed. Although it is logical that inhibition should minimize side effects,

there is some suggestion that complete inhibition of COX-2 may not be optimal for either the joint or the horse.⁹⁻¹¹ Whereas COX-1 is mainly responsible for the protective functioning of prostaglandins, COX-2 may play an accessory constitutive role in the COX pathway.

The mainstream view is still that the beneficial effects of selective COX-2 inhibition in OA are ideal. Anecdotally, carprofen (Rimadyl, Pfizer, New York, New York, United States) was used at CSU in horses that developed high serum creatinine levels and diarrhea in association with phenylbutazone use. These side effects disappeared when horses were given carprofen; a protective effect was seen, implying there may be more preferential COX-2 inhibition than with phenylbutazone therapy. Firocoxib, a member of the class of drugs that selectively inhibits the COX-2 isoenzyme, is now approved for use in horses to control pain and inflammation associated with OA in general, and its pharmacokinetics during prolonged use have been determined.¹²

Although prostaglandin inhibition provides effective symptomatic relief, there may be long-term deleterious effects of some NSAIDs on cartilage metabolism.¹¹ In vitro work in the horse had initially shown no evidence of deleterious effects on cartilage metabolism.¹³ However, in a more recent study, phenylbutazone was given to horses for 14 days, and serum was tested on articular cartilage explants in vitro. There was decreased proteoglycan synthesis to a degree similar to that with recombinant human interleukin-1 β .¹⁴ However, in the absence of any clinical associations between phenylbutazone use and articular cartilage degeneration, continued appropriate use of NSAIDs is justified.

A new, licensed topical NSAID preparation, 1% diclofenac sodium cream (Surpass, IDEXX Laboratories, Greensboro, North Carolina, United States), is now available in the United States but not in Europe. Previous research in people indicated topical NSAID could be clinically beneficial while reducing systemic side effects. Antiinflammatory effects were demonstrated experimentally using an induced subcutaneous inflammation model.¹⁵ A clinical field trial of the topically applied diclofenac liposomal cream for the relief of joint inflammation showed promising results,¹⁶ and more recently its value was demonstrated in equine OA using an osteochondral fragment–exercise model (see the section on Intraarticular Corticosteroids).⁸

Intraarticular Corticosteroids

The use of intraarticular corticosteroids for treatment of equine OA was extensively reviewed in 1996, and the benefits and deleterious side effects were more recently clarified.¹⁷ Based on my observation of an apparent lack of correlation between the previous use of betamethasone esters (Betavet Soluspan, Schering-Plough Animal Health Corp., Union, New Jersey, United States) and articular cartilage degradation during arthroscopic surgery for osteochondral chip removal, experimental studies were initiated for the three most commonly used intraarticular corticosteroids. Methylprednisolone acetate (MPA) (Depo-Medrol, Pharmacia and Upjohn Co., Kalamazoo, Michigan, United States), triamcinolone acetonide (TA) (Vetalog, Bristol Myers Squibb for Fort Dodge, Fort Dodge, Iowa, United States), and betamethasone esters (Betavet Soluspan) were evaluated using an osteochondral fragment–exercise model.¹⁸⁻²⁰ Betamethasone (Betavet Soluspan, now available as Celestone Soluspan) was tested first. Osteochondral fragments were created arthroscopically on the distal dorsal aspect of the radial carpal bone in both middle carpal joints in 12 horses, and one joint was treated with 15 mg of betamethasone at 14 and 35 days after surgery.¹⁸ The contralateral control middle carpal joint was injected with saline. No deleterious side effects on articular cartilage were demonstrated. Exercise produced no harmful effects in the presence of betamethasone.¹⁸

In subsequent studies with intraarticular corticosteroids (as well as other treatments), the research model was modified so that the contralateral joint was not used as a control. The chip fragment model was also modified to more effectively produce early osteoarthritic change. Eighteen horses were randomly assigned to three groups: MPA or TA was injected 14 and 28 days after surgery, and horses were exercised on a high-speed treadmill for 6 weeks, beginning on day 15 after surgery. Results were compared with control joints treated with corticosteroids but which had no osteochondral fragment, as well as with a second control osteochondral fragment group treated with polyionic fluid (Figure 84-1).^{19,20} In joints containing an osteochondral fragment and treated with MPA, there was a trend (not statistically significant) for lower lameness scores. However, there were significantly lower synovial fluid PGE₂

Fig. 84-1 • Design of experiments to assess the value of direct intraarticular injection of a corticosteroid into an osteoarthritic joint (ST TX), as well as injection of intraarticular corticosteroid in a remote joint (ST CNT) compared with a saline-injected control (CNT). (Reproduced with permission. McIlwraith CW: From arthroscopy to gene therapy—30 years of looking in joints, *Proc Am Assoc Equine Pract* 51:65, 2005.)

concentrations and lower scores for intimal hyperplasia and vascularity (no effect on cellular infiltration in the synovium compared with placebo-treated joints) in MPA-treated joints compared with control joints. Of more importance, modified Mankin scores (a score of histopathological change in articular cartilage) were significantly increased in MPA-treated joints compared with control joints, suggesting deleterious effects of intraarticular administration of MPA.¹⁹ This is in contrast to the results with TA (Vetalog).²⁰ Horses that were given 12 mg of TA in a joint containing a fragment (TA TX) were less lame than horses in the two control groups (see [Figure 84-1](#)). Horses treated with TA had lower protein and higher hyaluronan (HA) and GAG concentrations in synovial fluid. Synovium from treated groups had less inflammatory cell infiltration, intimal hyperplasia, and subintimal fibrosis. Analysis of articular cartilage morphological parameters evaluated using a standardized scoring system was significantly better from TA control (no fragment) and TA treatment groups compared with the control placebo-treated fragment group. The results supported favorable effects of TA on lameness scores, synovial fluid, synovium, and articular cartilage morphological parameters, both with direct intraarticular administration and remote site administration compared with placebo injections.²⁰ Evaluation of intraarticular TA on subchondral bone showed no deleterious effects.²¹ In other work, repetitive intraarticular administration of MPA to exercising horses altered mechanical integrity of articular cartilage but had no effect on subchondral or cancellous bone.²³

Based on these and recent *in vitro* results demonstrating a protective effect of TA,²⁴ I recommend TA be used especially in high motion joints. Some have recommended low doses of MPA to alleviate potential negative effects. However, based on *in vitro* titration studies, commonly used “low doses” are unlikely to have the same clinical effects because a greater concentration of corticosteroid is needed to inhibit the catabolic compared with the anabolic effects on articular cartilage.²⁵ On the other hand, clinical improvement is seen in horses administered low doses, an observation that is more important to a clinician than are experimental data.

Despite scientific studies demonstrating the efficacy and chondroprotective properties of TA, some practitioners fear the potential of TA to cause laminitis. Laminitis did not occur in 1200 horses treated with TA when the total dose did not exceed 18 mg.²⁶ From this study, 18 mg was established as a maximum dose. A more recent study reported no association between the occurrence of laminitis and the intraarticular use of TA.²⁷ There was a recent legal case in the United Kingdom in which a horse developed catastrophic laminitis after receiving 8 mg of TA in each tarsus and 20 mg of dexamethasone into its back.²⁸ This led to a review of the literature, which revealed that there was a lack of good evidence linking laminitis to corticosteroid injection; it was suggested that a large-scale multicenter trial was needed.²⁹ A related retrospective study from one clinician^{29,30} revealed that laminitis associated with intraarticular injection of corticosteroids had occurred in 3 of 2000 (0.15%) horses. TA was used the majority of the time, and the upper total dose ranged from 20 to 45 mg.³⁰ The relationship between corticosteroid use and laminitis is discussed further in Chapter 34.

Another traditional cliché is that although it is better not to use MPA in high-motion joints, using it in

low-motion joints (such as the distal tarsal joints) is appropriate. This implies that we do not care about the state of the articular cartilage in these joints, and perhaps corticosteroids may promote ankylosis. There is currently no evidence that ankylosis can be promoted in this fashion. The other side of this argument is that we should preserve articular cartilage whenever we can. Intraarticular injection of MPA or TA (with or without hyaluronan [HA]) in horses with OA of the distal hock joints led to a positive outcome in only 38% of horses (suggesting to the authors that surgical treatment may lead to better long-term prognosis).³¹ There was no significant difference between treatment with either MPA or TA, thus questioning any clinical advantages of the use of MPA.³¹ However, this was a relatively small study performed on a referral population of horses, and these results may not be representative of the overall response of horses with distal hock OA to intraarticular medication.

Intraarticular corticosteroids are commonly combined with HA, and there is a perception that the HA might be protective against any deleterious effects of corticosteroids (MPA). This perception is based on tradition rather than scientific proof but has become common thinking among equine practitioners.³ Some support can be gained from a 1-year, single-blind, randomized study in which 24 human patients were treated with intraarticular HA once weekly for 3 weeks and then again at 6 months (total of six injections).³² Sixteen of these patients also had TA before the first and fourth HA injections, and using the Western Ontario and McMaster Universities Index of OA (WOMAC) scores, the results were better with the combination of these two products. There was no progression of OA as evaluated using magnetic resonance imaging in either group.³² Two *in vitro* equine studies evaluated whether HA might have a mitigating effect against the deleterious effects of MPA. In the first study, HA addition had little effect on MPA-induced cartilage matrix proteoglycan catabolism in cartilage explants.³³ In the second study, MPA combined with HA had beneficial effects on proteoglycan metabolism in interleukin-1 (IL-1)-treated equine chondrocytes (but there were no comparisons between HA alone and MPA plus HA).³⁴ The combination of MPA and HA increased PG synthesis compared with IL-1-treated controls.³⁴

Hyaluronan (Sodium Hyaluronate)

HA is a nonsulfated GAG, and the biological characteristics and therapeutic use of HA in equine OA were reviewed previously.^{35,36} HA has modest analgesic effects,³⁷ but more emphasis is placed on its antiinflammatory effects that may be physical (steric hindrance) or pharmacological (inhibition of inflammatory cells and mediators).³⁶ Various *in vitro* studies have shown HA protects against IL-1-driven prostaglandin synthesis and inhibits free radicals, but the ability of HA to inhibit matrix metalloproteinase (MMP) activity is questionable.^{38,39} Several inflammatory mediators can augment HA production by synovial fibroblasts *in vitro*; therefore elevated synthesis of HA in early OA may constitute a protective response by the synovium to joint inflammation.³⁶ While providing a rationale for exogenous administration, it may explain the elevated levels of HA in response to intraarticular injection of a number of medications.^{19,20}

In my opinion, HA alone is useful in horses with mild to moderate synovitis, but the adjunctive use of corticosteroids is necessary in most horses with OA. However, based

on clinical evidence in people, although the immediate effects may not be dramatic, the evidence for long-term disease-modifying activity of HA is accumulating.⁴⁰ Claims that HA preparations of molecular weight exceeding 1×10^6 Da may provide superior clinical results and chondroprotection than lesser-molecular-weight products remain controversial.^{36,41,42}

In a randomized, double-blind, and placebo-controlled clinical study, 77 Standardbred trotters with moderate to severe lameness were treated with HA, polysulfated glycosaminoglycan (PSGAG), or placebo for 3 weeks. Mean initial lameness score was significantly reduced during treatment and at the last examination in all three groups ($P < 0.01$).⁴³ Additionally, the prevalence of sound horses increased significantly from 1 to 3 weeks of treatment into the last examination in all three groups. Both drugs (250 mg of PSGAG intraarticularly four times or 20 mg of HA intraarticularly twice) were superior to placebo for reduction of lameness score during treatment and the total study period, time until soundness occurred, and the number of sound horses at the last examination. Thus placebo and drug therapy were effective in the treatment of naturally occurring traumatic arthritis in horses, but HA and PSGAG gave better results than placebo. In a second study, the researchers compared intraarticular saline with rest alone in 38 Standardbreds with traumatic arthritis.⁴⁴ The mean lameness was significantly lower when 2.0 mL of 0.9% NaCl solution was injected compared with control horses.⁴⁴ This raises the question: is this effect the result of withdrawing fluid and/or placing a needle in the joint?

Most recently, intraarticular HA was tested in the CSU equine OA model.⁴⁵ OA was induced by the osteochondral fragment-exercise model in one middle carpal joint of 24 horses. Eight horses received HA (20 mg) (Hyvisc, Boehringer Ingelheim GmbH, Ingelheim am Rhein, Germany) and amikacin (125 mg) intraarticularly on study days 14, 21, and 28. A second group of eight horses received PSGAG (250 mg) and amikacin (125 mg) intraarticularly on study days 14, 21, and 28. The remaining eight horses were control horses. There were no adverse treatment-related problems. Synovial effusion was reduced with PSGAG compared with controls. No changes in other clinical signs (lameness, response to flexion, joint effusion, and radiological findings) were seen with PSGAG or HA compared with controls. Histologically, however, there was significantly less articular cartilage fibrillation seen with HA treatment compared with controls (despite no significant reduction in vascularity and subintimal fibrosis of the synovium). The conclusion was that HA had beneficial disease-modifying effects and was a viable therapeutic option in equine OA.⁴⁵ The result of a questionnaire survey of 20 members of the American Association of Equine Practitioners (14 responses) showed that it was uncommon for the respondents to administer intraarticular HA initially or alone, particularly in horses with established OA.³ Twelve of 14 supplemented HA injections with other forms of treatment (usually intraarticular corticosteroids).³

The use of intravenous HA (Legend [or Hyonate], Bayer HealthCare LLC, Animal Health Division, Shawnee Mission, Kansas, United States) in the treatment of OA is now common. Using intravenous HA in the experimental osteochondral fragment-exercise model, there was significant improvement in clinical lameness, decreased PGE_2 , and total protein levels in the synovial fluid, as well as decreased

hyperemia and cellular infiltration of the synovium.⁴⁶ However, in a survey, most clinicians were not impressed by the efficacy of intravenous HA and its short duration of action in the treatment of OA, particularly when used alone.³

Based on the reports from the manufacturing company, the majority of intravenous HA is used "prophylactically" in athletic horses with the attributed benefits being subjective. The prophylactic value of intravenous HA was studied in both Quarter Horse and Thoroughbred racehorses. One hundred and forty horses participated in the Quarter Horse study and received either intravenous saline or HA every 2 weeks for the duration of the 9-month study.⁴⁷ Trends for HA-treated horses to race longer, require an intraarticular injection of corticosteroid earlier, have a better speed index, have a higher average number of starts, and earn more money were observed when compared with placebo-treated horses. The Editors note that the better performance results could be due to earlier corticosteroid treatment in the HA-treated compared with placebo-treated horses. A second unpublished study was conducted in Thoroughbred racehorses using synovial fluid markers and starting with horses without musculoskeletal problems. No significant differences were found between HA- and placebo-treated horses. However, there are anecdotal positive reports regarding the prophylactic use of intravenous HA from trainers in various equine disciplines.

Polysulfated Glycosaminoglycan

PSGAG belongs to a group of polysulfated polysaccharides and includes, in addition to PSGAG (Adequan, Luitpold Pharmaceuticals Inc., Animal Health Division, Shirley, New York, United States), pentosan polysulfate. These drugs are DMOADs, and therefore PSGAG has been traditionally used when cartilage damage is presumed present rather than in the treatment of acute synovitis.⁴⁸ However, recent work questions this traditional approach (see below). Use of DMOADs is meant to prevent, retard, or reverse the morphological cartilaginous lesions of OA, with the major criterion for inclusion being prevention of cartilage degeneration. The principal GAG in PSGAG is chondroitin sulfate (CS), and the product is made from an extract of bovine lung and trachea modified by sulfate esterification.

Adequan was reviewed extensively in 1996.⁴⁸ One in vitro study demonstrated that PSGAG was the only drug tested (others included phenylbutazone, flunixin meglumine, betamethasone, and HA) that inhibited stromelysin.⁴⁹ There have been three other in vitro studies on the effect of PSGAG on equine cartilage that had contradictory results. PSGAG caused increased collagen and GAG synthesis in both articular cartilage explants and cell cultures from normal and osteoarthritic equine articular cartilage.⁵⁰ However, other work found a dose-dependent inhibition of proteoglycan synthesis, little effect on proteoglycan degradation, and no effect on proteoglycan monomer size.⁵¹ Various studies have supported the value of intraarticular PSGAG (250 mg) in equine OA, including a clinical study,⁵² a study using a Freund's adjuvant-induced OA model,⁵³ and a carpal synovitis model using sodium monoiodoacetate.⁵⁴ In the latter study, there was significant reduction of articular cartilage fibrillation erosion, less chondrocyte death, and markedly improved GAG staining.⁵⁴ However, PSGAG had no benefit in healing preexisting articular cartilage lesions in the latter study⁵⁴ or in a different study in ponies.⁵⁵

I have traditionally recommended the use of intraarticular PSGAG after arthroscopic surgery when there is substantial loss of articular cartilage (most commonly in the carpus). I observed rapid resolution of synovitis and hemarthrosis after PSGAG administration that otherwise tended to be persistent after arthroscopy when there was secondary loss of articular cartilage. A recent study using the CSU equine osteochondral fragment-exercise model compared intraarticular PSGAG with either intraarticular HA or saline and revealed that synovial fluid effusion was significantly reduced with PSGAG compared with both saline and HA. The degree of vascularity and subintimal fibrosis of the synovium was significantly reduced with PSGAG treatment compared with controls.⁴⁵ The main value of intraarticular PSGAG appears to be for severe (and acute) synovitis (most commonly seen after arthroscopic surgery when there is considerable debridement of bone). However, the U.K. data sheet expressly states, "Do not inject into actively inflamed joints. In the presence of active joint inflammation, therapy with a suitable anti-inflammatory drug should be given prior to intraarticular treatment with Adequan."

Administration of PSGAG intramuscularly has become popular. However, intramuscular PSGAG (500 mg every 4 days for seven treatments) produced relatively insignificant effects in horses with sodium monoiodoacetate-induced synovitis (limited to slightly improved GAG staining).⁵⁶ In a more recent study using the osteochondral fragment-exercise model in which intramuscular PSGAG was used as a positive control (administered every 4th day for 28 days starting 14 days post-OA induction), decreased GAG levels in the serum 14 days posttreatment was the only significant beneficial effect.⁵⁷ In this study, better improvement was seen in horses given extracorporeal shock wave therapy.

In a 1996 survey, PSGAG was considered more effective than HA for the treatment of subacute OA and less effective for idiopathic joint effusion and acute synovitis⁵⁸; however, there is currently only weak evidence to justify intramuscular administration. It was reported that articular cartilage concentrations of PSGAG after intramuscular administration are capable of inhibiting some cartilage degrading enzymes,⁵⁹ but the duration of effective concentration is unclear. A number of articular degradative enzymes were reduced in an *in vitro* study in other animals, but direct evidence of effectiveness in the horse is lacking.^{59,60}

In the questionnaire survey of veterinarians cited previously, indications for use of intramuscular PSGAG varied widely, including acute and/or chronic OA.³ PSGAG was also used as a preventative measure, and information from the manufacturer reports that 90% of sales are for such "prophylactic" use. There have been no scientific studies on prophylactic use, and efficacy is difficult to prove or disprove.

A principal driving force for the persistent use of intramuscular PSGAG in preference to intraarticular administration is the work demonstrating a slightly increased risk of infection following intraarticular injection compared with corticosteroids and HA.⁶¹ However, a companion study found that all risks could be obviated with concurrent intraarticular injection of amikacin sulfate, 125 mg (0.5 mL).⁶² In a survey of 20 practitioners, it was reported that six of seven racehorse veterinarians used intraarticularly administered PSGAG, at least occasionally, whereas a

similar number of nonracehorse veterinarians avoided the practice.³ Intraarticular use of PSGAG is still common in Europe. A recent multivariable analysis of factors influencing the outcome of two treatment protocols in 128 horses responding positively to intraarticular analgesia of the distal interphalangeal joint showed significant positive effects with an intraarticular PSGAG therapy protocol of three intraarticular injections approximately 8 days apart.⁶³ Antimicrobial drugs were not administered, and no adverse results were reported.

Pentosan Polysulfate

The use of pentosan polysulfate (PPS) was reviewed in 1996, but at that time reports of its efficacy were only anecdotal.⁶⁴ PPS is a heparinoid compound but is unique because it is derived from beechwood hemicellulose instead of animal sources. Commercial products available include Cartrophen Vet (Biopharm, Australia Pty Ltd, Bondi Junction, NSW, Australia) (licensed for use in small animals in Australasia and Europe, but not in horses) and more recently Pentosan Equine Injection (Nature Vet Pty Ltd., Glenorie, NSW, Australia; 250 mg/mL PPS sodium), which is licensed in Australasia. In experimental studies in sheep, weekly intraarticular injections of PPS for 4 weeks improved joint function and reduced mean radiological scores and Mankin histological scores of articular cartilage damage in femoral condyles.⁶⁵

Recently, we found favorable results using PPS given at a dose of 3 mg/kg body weight once weekly for 4 weeks (Pentosan Equine Injection). Using the carpal osteochondral fragment-exercise model, there was a significant decrease in articular cartilage fibrillation ($P < 0.05$) and a strong trend ($P = 0.06$) for improvement in overall cartilage histological appearance (modified Mankin score). Furthermore, although there was improvement in most other parameters (lameness, joint flexion, synovial fluid total protein concentration, synovial fluid collagen degradation products, and aggrecan synthesis), results were not statistically significant.

Combination Intraarticular Therapy

HA and corticosteroids are commonly combined. Without corticosteroids, the efficacy of intraarticular HA (based on short-term clinical response) is limited to horses with mild to moderate synovitis but is markedly enhanced with corticosteroids. Some veterinarians have used HA in conjunction with MPA, thinking that the former would mitigate the effects of the latter, but this is questionable (see page 842). In human medicine, localized, severe, acute inflammatory reactions (SAIRs) were associated with the use of highly cross-linked HA products.⁶⁶ Although no adverse reactions were reported using Hylan G-F 20 (Synvisc, Genzyme, Cambridge, Massachusetts, United States) in people with knee OA,⁶⁷ others have reported SAIRs and reduction of the risk with concurrent intraarticular corticosteroid administration.⁶⁸ The risk of adverse reactions after Hylan G-F 20 administration may increase with the second or third injection.⁶⁹ This may be because of an immunogenic mechanism associated with fermented HA products; the problem was not seen with naturally extracted HA.⁶⁹ Anecdotally, there have been more adverse reactions in horses following synthetic HA injections compared with naturally extracted HA. The combination of TA and

insulin-like growth factor-I (IGF-I) has been evaluated in vitro with positive results.⁷⁰

The Editors add that various other combinations of intraarticular products have been used by practitioners to manage horses with OA. A combination of hyaluronan and PSGAG (and amikacin sulfate) has been used, apparently quite safely, to manage chronic OA in Standardbred racehorses and anecdotal reports suggest this combination gives better results than injection of either product alone. Studies evaluating efficacy and safety of combination therapy have not been done. A new product, Polyglycan (Arthrodynamic Technologies, Versailles, Kentucky, United States), is a combination of HA, glucosamine, and CS and is marketed as a postsurgical lavage solution. This product is currently being used to manage OA in horses as an intraarticular or intramuscular injection and anecdotal reports suggest the efficacy of this combination approach is similar to that seen with PSGAG alone. Preliminary studies are underway.

Oral Joint Supplements

Oral joint supplements are loosely classified as nutraceuticals. The term “nutraceutical” combines the word “nutrient” (nourishing food or food component) with “pharmaceutical” (a medical drug)⁷¹ and describes a broad list of products sold under the premise of being a dietary supplement (i.e., a food) but for the expressed intent of treatment or prevention of disease. The claims (usually made by manufacturers) to aid in equine joint health are often very weak. Unlike a feed, a nutraceutical is unlikely to have an established nutritive value. Feeds are required to have nutritive value, and labels must be accountable. Joint supplements fall between food and drugs, and there is no requirement for labels to list ingredients or nutrient profiles as required for feeds. They are sold with the intent to treat or prevent disease without first undergoing proper drug approval.⁷¹ Joint supplements are fed to horses to heal the lame or make chronically unsound horses sound or to prevent joint problems from occurring. However, when an owner or trainer first uses oral supplements, the source of pain is rarely diagnosed. A role in prevention of OA is hard to disprove but serves as a rationale to use nutraceuticals and many licensed drugs. In 2005, nutraceutical sales in the United States reached more than 1 billion U.S. dollars for companion animals, and that figure was expected to double in the next 3 years. To equine practitioners, this is disturbing because this industry is, for the most part, unregulated by the Food and Drug Administration, and there is only weak in vivo scientific evidence to support use of their products.⁷²

None of the oral supplements or nutraceuticals are licensed, and proof of efficacy is generally lacking. Most products include variable amounts of glucosamine and/or CS along with other ingredients. The first oral GAG products available for equine use included a CS product extracted from bovine trachea (Flex-Free) and a complex of GAGs and other nutrients from the sea mussel *Perna canaliculus* (Syno-Flex)(Vita Flex Nutrition, Council Bluffs, Iowa, United States). More recently, glucosamine hydrochloride, CS, manganese, and vitamin C have been marketed as a nutraceutical (Cosequin) (Nutramax Laboratories, Inc., Edgewood, Maryland, United States), and a number of other products have simulated Cosequin. There are now many other commercially available products containing

various concentrations of glucosamine, chondroitin sulfate, manganese, vitamin C, methylsulfonylmethane (MSM), fish oils, and other constituents. The different labeling methods make it extraordinarily difficult to compare objectively the relative amounts of the different constituents between products. Glucosamine sulfate is a precursor of the disaccharide subunits of cartilage proteoglycans. Glucosamine salts are well absorbed orally in people⁷³; however, in the horse oral bioavailability of glucosamine hydrochloride was only 2.5%, interpreted as poor absorption, but with extensive tissue uptake thereafter.⁷⁴ In dogs, glucosamine is poorly absorbed when given orally (12%), probably because of extensive first-pass metabolism in the gastrointestinal tract and/or liver.⁷⁵

In a more recent study, eight adult female horses with no evidence of joint disease were randomly assigned to two groups (n = 4) in a crossover study.⁷⁶ Glucosamine hydrochloride (20 mg/kg) was administered by nasogastric intubation or intravenous injection. The maximum serum and synovial fluid glucosamine concentrations were substantially higher after intravenous administration ($288 \pm 53 \mu\text{M}$ and $250 \mu\text{M}$, respectively) than by the oral route ($5.8 \pm 1.7 \mu\text{M}$ and 0.3 to $0.7 \mu\text{M}$). The levels of glucosamine found in synovial fluid after oral administration were lower than those that have been used in vitro to study glucosamine action in tissue culture.⁷⁶

CS consists of alternating disaccharide subunits of glucuronic acid and sulfated N-acetylgalactosamine molecules and is a principal GAG of aggregating proteoglycan (aggrecan). CS is less sulfated but resembles PSGAG in structure and mechanism of action. Oral absorption of CS was tested in horses. A low-molecular-weight CS (0.80 kDa) was evaluated by quantifying the disaccharide content using a validated method that combined enzymatic digestion of plasma followed by fluorescence high-performance liquid chromatography.⁷⁷ Low-molecular-weight CS was absorbed better than glucosamine; its absorption may be influenced by the molecular weight of the polymer.⁷⁷

In vitro studies can potentially help to determine at what concentrations glucosamine or CS may inhibit a catabolic response in equine cartilage explants. A study of cartilage disks incubated with lipopolysaccharide (LPS) in varying concentrations of glucosamine, CS, or both revealed that glucosamine concentrations as low as 1 mg/mL decreased nitrogen oxide production, but that CS at either 0.25 or 0.5 mg/mL had no effect. Glucosamine concentrations as low as 0.5 mg/mL decreased PGE₂ production, whereas CS did not affect PGE₂ production. A combination of CS and glucosamine decreased MMP-9 activity but had no effect on MMP-2; there was a trend for decreasing MMP-13 protein concentrations.⁷⁸

In vitro dose titration studies of glucosamine hydrochloride and CS alone and in combination were performed in our laboratory. There were no detrimental effects of either glucosamine hydrochloride, CS, or a combination of both on normal cartilage metabolism. High doses of either glucosamine or CS or the combination limited total GAG release, whereas intermediate doses enhanced GAG synthesis and total cartilage content.⁷⁹ The same dosages tested on IL-1-conditioned articular cartilage explants revealed no treatment effects for either glucosamine or CS alone, but a protective effect of high doses of the two combined for total GAG release. This study suggested that

a combination of CS and glucosamine might be beneficial to cartilage metabolism by preventing GAG degradation. However, the question of effective concentration of glucosamine after oral administration remains an issue.⁷⁶

An oral HA product showed no efficacy in our osteochondral fragment–exercise model. However, a clinical study evaluating the use of an oral HA product after arthroscopic surgery for tarsocrural joint osteochondritis dissecans (OCD) revealed a significant reduction in post-operative synovial fluid effusion in treated horses compared with controls.⁸⁰

The osteochondral fragment–exercise model was used to test avocado and soybean unsaponifiable (ASU) extracts.⁸¹ The placebo control group ($n = 8$) received molasses orally once daily, whereas the ASU-treated horses ($n = 8$) received 6 g of ASU plus a similar volume of molasses orally. At the termination of the study, horses treated with ASU had significantly improved total gross examination score (articular cartilage erosion plus synovial hemorrhage score) in the OA joint compared with placebo control horses.⁸¹ There were significant decreases in synovial intimal hyperplasia and the cartilage disease score and a trend for decrease in lameness scores. Although improvement was modest, it was greater than that seen with other parenteral (intramuscular PSGAG and intravenous HA) and oral (HA) products tested using the same model.

Platinum Performance (Platinum Performance Inc., Buellton, California, United States) is a combination of rare earth minerals and omega-3 fatty acids that is used post-operatively, but all information is anecdotal. There is potential value of using omega-3 polyunsaturated fatty acids (PUFAs) in the management of OA. PUFA administration reduces inflammatory mediators in equine monocytes, corresponding to an increase in the ratio of omega-3 to omega-6 fatty acids in cell membrane phospholipids.^{77,78} In an *in vitro* study, the role of α -linolenic acid and omega-3 PUFA, as well as its antiinflammatory potential for the reduction of equine synovial inflammation, was evaluated in an established LPS model.⁷⁹ Whereas LPS significantly increased production of PGE₂ and decreased production of HA, treatment with α -linolenic acid at the highest dose inhibited prostaglandin production.⁷⁹

Summary of Use of Conventional Medications

Conventional medications still form a large part of the equine veterinarians' armamentarium. Increased attention is being paid to physical therapy regimens and positive results demonstrated with shock wave therapy (see [Poly-sulfated Glycosaminoglycan](#), page 843); these could possibly decrease the need for medication for equine joint disease. COX-2 inhibitors may be useful when a horse does not tolerate phenylbutazone well. Intraarticular corticosteroids continue to be the principal intraarticular therapy. The use of MPA has decreased appropriately, and the value of betamethasone esters and TA is recognized, but there is still an overuse of MPA, and I consider its use in high-motion joints to be below the standard of care. (One of the Editors [MWR] respectfully disagrees. Given the short-lived effect of TA, limited dosages [20 to 40 mg/joint] of MPA are still used in high-motion joints if a sustained effect of antiinflammatory therapy is needed.) Continued availability of licensed medication is a challenge. Intraarticular HA continues to be used in conjunction with corticosteroids. Recent research challenges the value gained from

intramuscular PSGAG, but results have been positive with intraarticular use of the drug. It is predicted that PPS will become a licensed medication, and its value has been documented scientifically. Oral nutraceuticals continue to be somewhat of a "black box" as far as efficacy is concerned, but positive results in a controlled study with avocado and soybean extracts are exciting.

The Editors respectfully point out that the osteochondral fragment–exercise model of OA is not necessarily representative of naturally occurring OA in sports horses. Although it is a reliably reproducible model of OA, drugs may have a different effect in naturally occurring OA compared with this experimental model. Comparisons between the efficacy of various drugs and other treatment modalities using the experimental model are also not easily made because in most of the studies significant results are achieved with the tested drug compared with control horses for one or more of the many measured parameters. The studies are relatively short term compared with the career of many equine athletes and only assess short-term outcomes. The studies using this model have unquestionably enhanced knowledge about the potential efficacy of a variety of drugs, but these results are not necessarily transferable to all high- and low-motion joints with naturally occurring OA.

NEWER BIOLOGICALLY BASED THERAPIES

Biological therapy specifically modulates key mediators, and our improved understanding of critical mediators in equine traumatic arthritis and OA has led to the identification of new targets for therapy. Two obvious targets identified include MMPs and IL-1.

Inhibition of Metalloproteinases as a Therapeutic Approach

MMP inhibitors include peptide-based (including hydroxamic acids), non-peptide-based (including chemically modified tetracyclines such as doxycycline), and naturally occurring inhibitors (such as omega-3 fatty acids, i.e., fish oils; see the section on [Oral Joint Supplements](#)).

In vitro studies assessed the MMP inhibitor BAY 12-9566 using an IL-1 degradation model (tenfold concentration [1 nM:10 μ M] increases) in equine and canine articular cartilage explants.⁸⁵ There was a significant dose-dependent reduction in the catabolic effect of IL-1 α on the release of proteoglycans and type II collagen. *In vivo* assessment of MMP inhibition has not been performed in the horse. However, a canine study of experimentally induced OA (cranial cruciate ligament transection) failed to demonstrate efficacy with an MMP inhibitor,⁸⁶ and the prospect for these being valuable therapeutically in the horse seems low.

Inhibiting Interleukin-1

The most commonly accepted mediator at the top of the cascade for cartilage degradation in OA is IL-1. However, tumor necrosis factor (TNF) has received most attention in rheumatoid arthritis in people, leading to the novel therapy of using an anti-TNF monoclonal antibody adalimumab (Humira, Abbott Laboratories, Abbott Park, Illinois, United States) and recombinant human TNF receptor etanercept (Enbrel, Wyeth Pharmaceuticals, Madison, New Jersey, United States).⁸⁷

IL-1 activates MMP, aggrecanase, and PGE₂ release by acting through IL-1 receptors on the cell membrane ([Figure](#)

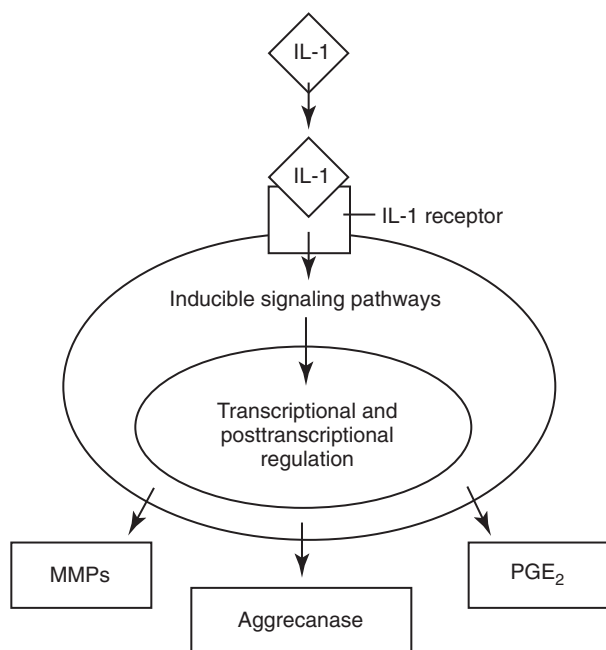

Fig. 84-2 • Diagram of interleukin-1 (IL-1) activation of metalloproteinase, aggrecanase, and prostaglandin E₂ release acting through IL-1 receptors on the cell membrane. (Reproduced with permission. McIlwraith CW: From arthroscopy to gene therapy—30 years of looking in joints, *Proc Am Assoc Equine Pract* 51:65, 2005.)

84-2). IL-1 can be inhibited through the natural antagonist, IL-1 receptor antagonist (IL-1ra), which binds to the cell membrane IL-1 receptor to block IL-1. IL-1 can also be inhibited by using soluble receptors, where IL-1 receptors are released from the cell membrane and bind IL-1.⁸⁷ Soluble receptors are used to inhibit TNF, but there are no current techniques for using IL-1-soluble receptors therapeutically. Cell membrane IL-1 receptors can be inhibited by using recombinant proteins or gene therapy (see Chapter 63). The first therapeutic application of IL-1ra for equine use involved the direct transfer of the equine IL-1ra gene sequence to synoviocytes using an adenoviral vector.^{88,89} Complete inhibition of carpal OA confirmed the critical role of IL-1 in the osteoarthritic process.⁸⁹ Although both symptom- and disease-modifying effects were demonstrated and the magnitude of therapeutic value was greater than any other medication tested to date, repeated delivery of IL-1ra using gene transfer necessitates a better vector, which is currently being researched.

The limitations with gene transfer therapy have led to the development of alternative methods of delivering IL-1ra to joints. The concept of IL-1ra, IRAP (Arthrex Vet Systems, Naples, Florida, United States) was developed in Europe as a product named Orthokine (Orthogen AG, Dusseldorf, Germany). To make IRAP, peripheral blood is collected in a syringe containing glass beads soaked in chromium sulfate and is incubated for 24 hours and is then centrifuged. The autologous modified serum (autologous conditioned serum [ACS]) is then used for one or more intraarticular injections. Marked elevation of IL-1ra without elevated expression of IL-1 or TNF, that is, preferential up-regulation of “good” cytokines without concurrent up-regulation of “bad” cytokines, was documented.⁹⁰ In 2004, Arthrex Biosystems began marketing IRAP in the United States, and their unpublished data confirmed up-regulation

of IL-1ra but not to the same extent as previously reported.⁹⁰ Up-regulation of proteins is probably through stimulation of monocytes by the beads and syringe, and it is likely that more than IL-1ra is up-regulated, a concept currently being studied at CSU using mass spectroscopy.

IRAP was tested in a double-blinded, placebo-controlled, experimental study using the osteochondral fragment-exercise model and was shown to have both symptom and disease-modifying effects in horses.⁹¹ In eight placebo and eight ACS-treated horses, 6 mL of phosphate-buffered saline (PBS) solution or ACS, respectively, was injected into the OA-affected joint on days 14, 21, 28, and 35. No adverse treatment-related events were detected. Horses that were treated with ACS had significant improvement in lameness scores, significantly decreased synovial hyperplasia, and less gross cartilage fibrillation and synovial hemorrhage than PBS-injected horses. Synovial fluid concentration of IL-1ra (assessed using a mouse anti-IL-1ra antibody) was increased after treatment with ACS.⁹¹ All reports concerning clinical efficacy of ACS are anecdotal; there have been no controlled clinical trials.

Mesenchymal Stem Cells

Mesenchymal stem cells (MSCs) have been used intraarticularly in the horse for a number of “indications.” Both clinical experience and research studies are limited to adult-derived MSCs, and bone marrow remains the gold standard as a source of MSCs. However, other sources such as muscle, cartilage, and adipose tissue contain multipotent MSCs. MSCs from bone marrow or digestive tissue are isolated by simple adhesion and proliferation of MSCs to tissue culture surfaces, a technique that yields a near-homogenous MSC population and is called culture expansion.⁹² Work is proceeding on establishing cell surface antigens that characterize MSCs. There are distinct differences between cultured-expanded MSCs and those available through non-culture-expanded sources, such as the Vet-Stem technique (Vet-Stem Regenerative Veterinary Medicine, Poway, California, United States), in which harvested fat undergoes tissue digestion, producing a nucleated cell population called stromal vascular fraction. Stromal vascular fraction is believed to contain approximately 2% to 4% MSCs. Much of the other literature regarding culture-expanded adipose-derived MSCs cannot necessarily be compared with the Vet-Stem technique.

Intraarticular use of MSCs was investigated in a study comparing adipose-derived stromal cells, bone marrow-derived cultured MSCs, and placebo in the equine osteochondral fragment-exercise model. There were no significant treatment effects in any group, with the exception of improvement in synovial fluid PGE₂ levels in horses treated with bone marrow-derived MSCs compared with the placebo group.⁹³ Based on this study, we cannot recommend the use of MSCs for the treatment of OA. However, the results of an ovine OA model using medial meniscectomy and cranial cruciate ligament transection, evaluating intraarticular autogenous bone marrow-derived MSCs, were encouraging.⁹⁴ There was regeneration of the medial meniscus and decreased progression of OA. Meniscal regeneration could be critical in decreasing OA in this model, whereas OA in the equine osteochondral fragment-exercise model has a different pathogenic pathway. Based on the ovine study, considerable interest was generated at CSU in using intraarticular MSCs to treat soft tissue injuries

in the femorotibial joints after arthroscopy, apparently with good clinical results.

Calcitonin

There is some evidence to suggest a direct chondroprotective effect of calcitonin, which, together with its well-established effects on bone resorption, makes it a potential biological therapy for OA.^{95,96} Calcitonin is used to treat osteoporosis.⁹⁷ In some in vitro work, calcitonin was shown to attenuate collagenase activity, targeting type II collagen.⁹⁸ Dogs with OA induced using the cranial cruciate ligament transection model given 400 U/day of calcitonin had significantly reduced histological changes in the articular cartilage of unstable knees. Calcitonin enhanced HA content, as well as the size distribution and relative abundance of aggrecan aggregates in cartilage in both operated and nonoperated knees. In the calcitonin group, the cartilage content of keratin sulfate increased in the operated joints.⁹⁶

Radiation Synovectomy

Synovectomy is hardly a specific biological therapy but is included so its potential use can be recognized. Synovectomy is a well-developed technique for removal of synovial-based inflammation in people with rheumatoid arthritis, but surgical synovectomy is technically difficult, time consuming, and requires general anesthesia.⁹⁹ Samarium-153 (¹⁵³Sm) bound to hydroxyapatite microspheres (¹⁵³SmM) effectively ablated normal equine synovium, with minimum radiation hazards to the horse or medical personnel.⁹⁹ Radiation emissions from ¹⁵³SmM are primarily absorbed by synovium; thus the clinician can target this intraarticular tissue specifically. ¹⁵³Sm-hydroxyapatite complex minimizes exposure to other organs or support personnel. In another study, the effects of ¹⁵³SmM on reactive synovium in a surgically induced model of synovitis were investigated.¹⁰⁰ Although there was a transient flare causing lameness, effusion, and edema for 48 to 72 hours, ¹⁵³SmM destroyed inflamed synovium. There may be potential (with further testing) for radiation synovectomy in horses with persistent synovitis unresponsive to conventional therapy.¹⁰⁰

SURGICAL TREATMENT

Arthroscopy has revolutionized management of joint disease (see Chapter 23).¹⁰¹⁻¹⁰³ Readers are referred to *Diagnostic and surgical arthroscopy in the horse*¹⁰⁴ for details including advantages and disadvantages of the technique. Arthroscopic surgery remains the gold standard for diagnosis and assessment of pathological joints. Diagnostic arthroscopy is especially valuable when response to medical treatment of a joint is suboptimal. In many instances, cartilage lesions are more extensive than suggested from radiographs but are consistent with the degree of clinical signs.

By 1990, equine arthroscopy had gone from being a diagnostic technique used by a few veterinarians to the accepted way of performing joint surgery.¹⁰¹ Prospective and retrospective data substantiated the value of arthroscopy in management of carpal chip fractures,¹⁰⁵ fragmentation of the dorsal margin of the proximal phalanx,¹⁰⁶ carpal slab fractures,¹⁰⁷ OCD of the femoropatellar^{108,109} and scapulohumeral¹¹⁰ joints, subchondral cystic lesions of the femur,¹¹¹ and various manifestations of osteochondrosis of the tarsocrural joint.¹¹² Diagnostic arthroscopy led to the

recognition of previously undescribed articular lesions, many of which are treated using arthroscopic techniques.

Since 1990, there have been further advances in diagnosis and management of joint disease based on new pathobiological knowledge gained from arthroscopy.^{102,113-118} Previously thought of as inaccessible, the palmar aspects of the carpal and distal interphalangeal joints are now routinely evaluated arthroscopically.¹¹⁹⁻¹²¹ Arthroscopy led to the discovery of soft tissue injuries, previously undiagnosed, such as tearing of the medial palmar intercarpal ligament.¹²²⁻¹²⁶ In the fetlock joint, we now know success rates after arthroscopy for horses with osteochondral fragments of the palmar/plantar aspect of the proximal phalanx,^{127,128} treatment of OCD of the distal dorsal aspect of the third metacarpal/metatarsal bones,¹²⁹ and apical, abaxial, and basilar fragments of the proximal sesamoid bones.¹³⁰⁻¹³⁴ The arthroscopic approach to the plantar pouch of the tarsocrural joint first documented in 1990¹⁰¹ was more recently reviewed.¹³⁵

Considerable advances have been made in arthroscopic surgery of the stifle joint. Results for the management of OCD of the femoropatellar joint and a syndrome of fragmentation of the distal aspect of the patella occurring after medial patellar desmotomy and success when treating certain patellar fractures were documented.^{101,136-138} The use of arthroscopic surgery to treat subchondral cystic lesions of the medial condyle of the femur¹³⁹ and proximal tibia¹⁴⁰ has been reported. In fact, pathogenesis of cystic lesions in the medial femoral condyle, once thought to only be a manifestation of osteochondrosis, was recently redefined. Subchondral cystic lesions were traumatically induced by surgically creating a defect, 3 mm deep and 5 mm wide, in the subchondral bone plate.¹⁴¹ Arthroscopic curettage and drilling into the cyst wall of naturally occurring subchondral cysts sometimes caused cyst enlargement and recurrent lameness; alternative methods for management have developed. Examination of the fibrous tissue of medial femoral subchondral cystic lesions demonstrated the production of local mediators and neutral MMPs, which caused bone resorption in vitro.¹⁴² Production of nitric oxide, PGE₂, and MMPs in media of explant cultures of equine synovium and articular cartilage has also been demonstrated in normal and osteoarthritic joints.¹⁴³ Therefore injection of corticosteroids into the lining membrane of subchondral cysts has been performed clinically with favorable results (Figure 84-3).¹⁴⁴

Cartilage lesions of the medial femoral condyle occur, but surgical manipulation is limited.¹⁴⁵ Adjunctive therapy using IRAP or MSCs has become popular, but results are anecdotal. Arthroscopy has allowed great advances in the recognition and treatment of meniscal tears and cruciate ligament injuries.¹⁴⁶⁻¹⁴⁸ Horses with grade I and grade II meniscal tears can be managed successfully, but those with lesions that are not completely accessible do not respond well (Figure 84-4). Arthroscopy has been used to facilitate removal and repair of fragments from the intercondylar eminence of the tibia.^{149,150} Techniques to manage disease of the caudal pouches of the femorotibial joints are now published.^{147,151-154} Limited diagnostic and surgical arthroscopy of the coxofemoral joint can be performed.^{155,156} Arthroscopy is no longer confined to the limbs, and the arthroscopic anatomy of the temporomandibular joint was described recently.¹⁵⁷

Fig. 84-3 • Arthroscopic view of an 18-gauge spinal needle being used to inject triamcinolone acetonide into the lining of a subchondral cystic lesion. (Reproduced with permission. McIlwraith CW: From arthroscopy to gene therapy—30 years of looking in joints, *Proc Am Assoc Equine Pract* 51:65, 2005.)

Arthroscopic-assisted repair with internal fixation of both nondisplaced and displaced articular fractures has become routine and includes fractures of the metacarpal/metatarsal condyles and carpal slab fractures (Figure 84-5).¹⁵⁸⁻¹⁶⁰ Techniques for evaluation and treatment of diseases of smaller joints¹⁶¹⁻¹⁶⁴ and in large joints in which lameness is seldom encountered are well developed.¹⁶⁵ Results of arthroscopic surgery are often limited by extensive cartilage damage, an observation that has led us back to scientific research as discussed below.

Recent Progress at Healing Articular Cartilage Lesions and Resurfacing Joints

Progressive loss of articular cartilage is the real challenge in horses with OA, and failure of osteochondral defects to heal is a major limiting factor in the prognosis after treatment of articular fractures. Arthroscopic techniques that enhance both the quantity and quality of cartilage repair tissue, while using the well-documented advantages of arthroscopic surgery, have been attempted.¹⁶⁶⁻¹⁶⁹ Repair, as

Fig. 84-4 • A grade II tear of the medial meniscus before (A) and after removal and debridement of the torn portion (B). (Reproduced with permission. McIlwraith CW: From arthroscopy to gene therapy—30 years of looking in joints, *Proc Am Assoc Equine Pract* 51:65, 2005.)

Fig. 84-5 • Arthroscopic view of a displaced fracture of the lateral condyle of the distal aspect of the third metacarpal bone before (A) and after (B) reduction: under arthroscopic guidance and internal fixation. occurs in full-thickness cartilage defects, is defined as replacement of damaged or lost cells and matrix with new cells and matrix, but the original structure and function may not be restored. Regeneration is a special form of repair, in which cells replace lost or damaged tissue with a tissue identical to the original, the aim of continuing investigations in resurfacing. Overall, attempts at improving the repair of articular defects can be divided into stimulation of endogenous repair and articular grafting.

Stimulation of Endogenous Repair

Stimulating endogenous repair involves techniques to provide access for marrow elements to populate the cartilage defect. The simplest method, debridement of the defect, provides fibrocartilaginous repair with high concentrations of type II collagen but low levels of proteoglycan (GAG).^{170,171} In addition to simple debridement, other methods of endogenous repair include partial-thickness chondrectomy, spongialization, subchondral bone drilling, abrasion arthroplasty, and most recently, micropicking or microfracture.

Debridement and the Need for Removal of Calcified Cartilage

The time-honored surgical principle of debridement to the level of subchondral bone is well known, but recent work at CSU revealed that if the calcified cartilage layer is left, healing is markedly restricted.^{169,172} If the calcified cartilage was removed, there was a significant increase in the amount of repair tissue in defects compared with controls at 4 and 12 months.¹⁷³ There was also significant enhancement of repair tissue attachment and calcified cartilage reformation in defects from which the calcified cartilage had been removed (Figure 84-6).

Partial-Thickness Chondrectomy

Partial-thickness chondrectomy down to relatively healthy chondral tissue (cartilage shaving) for partial-thickness defects and fibrillation smoothes the cartilaginous area and may decrease further tissue exfoliation, producing (in

conjunction with joint lavage) an early remission of synovitis. However, controlled work in the horse is still necessary. In rabbits in which articular cartilage was shaved on the underside of the patella, there was no evidence of repair.¹⁷⁴ Ultrastructural studies after arthroscopic cartilage debridement questioned any regeneration and suggested deleterious effects.¹⁷⁵

Spongialization, Abrasion Arthroplasty, and Subchondral Bone Drilling

Spongialization is removal of sclerotic subchondral bone from the base of a full-thickness defect, a procedure sometimes done in horses. However, subchondral bone cysts can form, and I believe that an intact subchondral bone plate is essential for maintaining a foundation for repair.

Abrasion arthroplasty, also called superficial intracortical debridement, as opposed to deep cancellous debridement, is used on sclerotic degenerative lesions in people.¹⁷⁶ The concept is controversial because it is necessary to expose cancellous bone to reach both blood supply and primitive MSCs. Critics have pointed to variables such as patient selection, arthroscopic debridement, and joint irrigation, as well as variation in the degree of pathological change in the joint.¹⁷⁷ In an in vitro study, low oxygen tension was demonstrated to be chondrotrophic and led to the corollary that excessive oxygen tension is not conducive to cartilage formation. Deep debridement to cancellous bone exposes the defect to blood and MSCs, but also to higher oxygen tensions; some people have questioned whether increasing oxygen tension to the defect is beneficial or not.¹⁷⁸ Follow-up biopsies after abrasion arthroplasty showed type I and type III collagen and only limited amounts of the much wanted type II collagen.¹⁷⁶

Subchondral drilling had similar rationale in providing access through the cancellous bone plate, while still preserving most of the subchondral bone plate. In a study on full-thickness defects of the third carpal bone of horses, satisfactory functional healing was not achieved.¹⁷⁹

Fig. 84-6 • Histology 12 months after articular cartilage defects in the medial femoral condyle were treated with microfracture and with the calcified cartilage removed (**A**) and retained (**B**). In addition to improved repair tissue, there is partial restoration of the calcified cartilage layer and better attachment of the repair tissue to the underlying bone in the section shown in **A**. Black arrows show the junction of repair tissue (left) and retained cartilage. White arrows in **B** show a micropick hole in subchondral bone. (Reproduced with permission. McIlwraith CW: From arthroscopy to gene therapy—30 years of looking in joints, *Proc Am Assoc Equine Pract* 51:65, 2005.)

Subchondral Micropicking (Microfracture)

Subchondral microfracture, or micropicking, was a technique developed by Dr. Richard Steadman and is extensively used in people.^{180,181} The technique was shown to provide equivalent repair to the commercially available autologous chondrocyte implantation process of Carticel (Genzyme, Cambridge, Massachusetts, United States).¹⁸² Micropicking is a simple and atraumatic way to provide pluripotential cells and growth factors while minimizing heat (associated with drilling with other techniques) and providing a rim of bone around the pick holes that may provide a foundation to enhance repair tissue attachment. Studies in the horse showed that the amount of repair tissue significantly increased when cartilage defects debrided down to subchondral bone were micropicked compared with debridement alone. A short-term study revealed that there was a significant increase in type II collagen mRNA production 8 weeks after microfracture.¹⁷² Although aggrecan production gradually increased between 2 and 8 weeks, this expression was not influenced by microfracture.¹⁷²

Further Manipulation of Endogenous Healing Using Growth Factors (Protein Administration or Gene Therapy)

We may be able to manipulate cells to produce improved repair tissue matrix. Several naturally occurring polypeptide growth factors play an important role in cartilage homeostasis.^{183,184} However, endogenous manipulation not only involves the use of growth factors to promote synthesis of matrix components (anabolism) but also should inhibit proteinases and inflammatory factors that can cause ongoing degradation after surgery (catabolism) (Figure 84-7). IGF-I and transforming growth factor- β (TGF- β) have matrix anabolic activity and are also considered important in counteracting the degradatory and catabolic activities of cytokines and MMPs. Three-dimensional cultures of equine chondrocytes in fibrin gels were evaluated with either IGF-I or TGF- β and cultured without serum supplements; these two growth factors stimulated matrix component elaboration in a dose-dependent manner, with the most profound effects occurring at the highest concentration of IGF-I and TGF- β .^{185,186} In other cartilage explant studies using normal and IL-1-depleted cartilage, IGF-I had a positive effect on equine cartilage homeostasis.¹⁸⁷ Because of these results, IGF-I was selected as a candidate growth

factor for evaluation in the horse. Elution studies showed that IGF-I-laden equine fibrin had maximal stimulatory levels of IGF-I (>50 ng/mL) remaining for a minimum of 3 weeks.¹⁸⁸ In vivo evaluation after placement of 25 μ g of IGF-I in fibrin into cartilage defects in the femoropatellar joint showed improved cell populations, with more cartilage-like architecture after 6 months.¹⁸⁹ However, type II collagen levels only increased to 47%, half of that found in normal articular cartilage, compared with a type II collagen content of 39% in the control defects, comparable with the levels seen in empty full-thickness defects.¹⁹⁰

Other work in the same laboratory suggested IGF-I worked better in combination with a chondrocyte or a MSC graft, resulting in more complete cartilage repair.¹⁹¹ At 8 months after implantation of a mixture of chondrocytes in 25 mcg of IGF-I in femoropatellar defects in horses, there was improved joint surface, 58% type II collagen, and better neocartilage integration at the defect edges. Resurfacing of articular defects using autogenous fibrin laden with 50 mcg of IGF-I in 30 million chondrocytes/mL of fibrin was used in horses with OCD and subchondral cystic lesion of the fetlock and stifle joints. The chondrocytes were mixed with fibrinogen and IGF-I with activated thrombin to provide a two-component system for immediate injection. This polymerization process developed immediately on injection into the articular defect.¹⁶⁷

Using gene therapy techniques (previously discussed with IL-1ra), transplanted chondrocytes were transfected with IGF-I.^{192,193} Transfecting transplanted chondrocytes with bone morphogenetic protein-7 accelerated cartilage repair.¹⁹⁴

In a collaborative effort between CSU, Cornell University, University of Pittsburgh, and Harvard University, the usefulness of a combined gene therapy protocol using IL-1ra to decrease the effects of IL-1 on cartilage repair in combination with IGF-I (previously shown to enhance cartilage healing in an equine model, as well as to also reduce the deleterious effects of IL-1) was investigated.¹⁹⁵⁻¹⁹⁷ Using an osteoarthritic IL-1 coculture (synovium and articular cartilage) system, gene transduction of IGF-I and IL-1ra proteins was demonstrated using an adenoviral vector with protection of proteoglycan loss in the cartilage.¹⁹⁵ There was also restoration of cartilage matrix without IL-1 present using the same in vitro system.¹⁹⁶ The combination gene therapy protocol was then evaluated using full-thickness articular

Fig. 84-7 • Diagram of homeostatic pathways that can represent potential ways of endogenously manipulating articular cartilage. IGF, Insulin-like growth factor; FGF-2, fibroblast growth factor-2; TGF- β , transformin growth factor- β ; BMPs, bone morphogenetic proteins; MMPs, matrix metalloproteinases; IL-1, interleukin-1. chondral defects treated with microfracture in the horse.¹⁹⁷ This protocol enhanced the quality of the repair tissue in full-thickness equine chondral defects compared with microfracture alone, and there was increased type II collagen and aggrecan content in the defects.¹⁹⁷

Articular Grafting

Reattachment of Cartilage Flaps and Periosteal and Sternal Grafts

Direct repair of large OCD defects by replacing the flap and providing fixation with polydioxanone (PDS) pins was done successfully in horses.¹⁹⁸ However, attempts with direct grafting of periosteum or sternal cartilage met with disappointing results.^{170,171,199}

Implantation of Autologous Chondrocytes

Early attempts at grafts of cultured chondrocytes or cartilage regenerative cells in a matrix were also relatively unsuccessful.²⁰⁰⁻²⁰² Currently there is one commercially available technique of autologous chondrocyte implantation into human knees, and it is used principally for focal erosive defects^{203,204} and OCD.²⁰⁵ This is a two-stage procedure. After collection of cartilage, it is cultured; 3 weeks later, a piece of autogenous periosteum is sutured into the defect, and the cultured chondrocytes are injected beneath it. Despite reports implying excellent results, failures, particularly with detachment of the graft, can occur, and recently a clinical study with a 2-year follow-up period showed no superiority over microfracture alone.¹⁸² Grafting in this manner was used experimentally in 10-mm-diameter defects on the lateral trochlear ridge of talus and resulted in significantly improved defect filling with a well-integrated neocartilage and comparable expression of cartilage-specific markers.²⁰⁶

I have conducted experiments at CSU using a solid form of autologous chondrocyte culturing. Cartilage (300 mg) was harvested from the lateral trochlear ridge of the femur, and chondrocytes were cultured on a collagen membrane and reimplanted at 4 weeks. The results were significantly superior to empty defects and defects implanted with matrix alone. However, it is still a two-stage technique, and this remains a caveat.²⁰⁷

A one-stage technique for treatment of 15-mm defects in the trochlear ridge of the femur in the horse was evaluated.²⁰⁸ An articular cartilage biopsy was taken from the

lateral trochlear ridge of the femur (follow-up evaluation at 12 months revealed no apparent morbidity associated with the cartilage biopsy). The cartilage was morselized into approximately 1 mm³ and suspended in fibrin on a membrane (a PDS-reinforced foam). This morselized cartilage-fibrin-PDS membrane combination was then placed into the defect with the membrane uppermost and fixed with three specially developed PDS-polyglycolic acid (PGA) staples. The follow-up results at 12 months were excellent. The technique is now being tested in people.

What about Stem Cells?

The use of MSCs in medical management of OA was previously discussed (see Mesenchymal Stem Cells, page 847). The relative chondrogenic potential of bone marrow-derived or adipose-derived MSCs was evaluated after expansion in monolayer culture and implantation into agarose or peptide gels.²⁰⁹ GAG accumulation in hydrogels seeded with culture-expanded MSCs and containing TGF- β after 21 days of culture was significantly enhanced with bone marrow-derived MSCs compared with adipose-derived MSCs, and there was also superior type II collagen expression. Implantation of MSCs (using fibrin as a vehicle) into femoral trochlear defects in the horse showed early benefit at 30 days, but there were no significant differences between treated and control joints at 8 months.²¹⁰ Direct intra-articular injection of MSCs is currently being tested at CSU. We contend that MSCs act as trophic mediators; in addition to dividing and differentiating, MSCs secrete a variety of cytokines and growth factors, and these bioactive factors suppress local immune reactions, inhibit fibrosis and apoptosis, enhance angiogenesis, and stimulate mitosis and differentiation of tissue-intrinsic reparative or stem cells.²¹¹ These effects, which are referred to as trophic effects, are distinct from the direct differentiation of MSCs into repair tissue.

Osteochondral Grafts

The use of osteochondral plugs to repair experimentally created defects in the medial condyle of the femur was initially investigated using sternal osteochondral grafts.^{212,213} Techniques of autogenous and allogeneic osteochondral plug grafting using mosaicplasty were reported with some success, but the technique is challenging.^{214,215}

Chapter 85

Analgesia and Hindlimb Lameness

Rose M. McMurphy

The benefits to providing analgesia for both acute and chronic pain are well established in many species. Inadequate treatment of pain can result in inappetence and

weight loss, increases in serum cortisol and catecholamines, tachycardia, hypertension, and compromise of the immune system.¹ Increases in serum cortisol and catecholamines can cause derangements in serum glucose, protein metabolism, and immune function. In addition, horses with a painful limb may remain recumbent for prolonged periods, with resultant decubital ulcer formation and secondary infection.

EPIDURAL ANALGESIA

Designing an appropriate plan for analgesia in a horse, particularly for those with severe, chronic pain, can be challenging. Parenterally administered opioids and

α_2 -adrenergic agonists may be associated with side effects such as ataxia, excitement, and adverse effects on the gastrointestinal and cardiovascular systems. Nonsteroidal antiinflammatory drugs (NSAIDs) can cause gastrointestinal ulceration or renal disease, and they may be inadequate for horses with acute, intense pain. Epidural administration of drugs provides more localized analgesia and fewer systemic effects than parenteral administration.

Epidural drug administration places a drug in close proximity to its site of action within the spinal cord or the spinal nerves as they exit the spinal cord. A greater analgesic effect may be achieved with a smaller total dose of a drug. The duration of analgesia is usually longer than with parenteral administration. Pain that is related to a disease process of a hindlimb is particularly amenable to treatment with epidural analgesia. The site of injection for epidural drug administration in horses is usually the first coccygeal (caudal) interspace. When deposited into the epidural space, the drug diffuses across the meninges, into the cerebrospinal fluid (CSF), and then into the spinal cord. The degree of cephalad diffusion of the drug within the CSF depends on several factors, including the volume of the drug injected, concentration of the drug, and lipid solubility.² Although studies in dogs and people have reported analgesic effects with epidural morphine or α_2 -agonists that extend to the midthoracic area or farther cranially,^{3,4} this is generally not the case in horses.⁵⁻⁸ This limits the use of epidural analgesia in horses to the treatment of hindlimb pain.

TECHNIQUE FOR EPIDURAL ADMINISTRATION

Caudal epidural drug administration can be done by single injection at the first coccygeal interspace or by placement of an epidural catheter at this same site for repeated drug administration. The lumbosacral space is also a potential site of injection, and its use may result in a more rapid onset of hindlimb analgesia. However, positioning the tip of the needle within the epidural space rather than the subarachnoid space can be difficult. Subarachnoid administration of drugs in the horse is certainly acceptable, but the dose should be reduced by 40% to 50%.

The first coccygeal interspace (between the first and second coccygeal vertebrae) is identified while raising and lowering the tail and palpating for the articulation between these two vertebrae. This space is just caudal to the most angular portion of the bend of the tail, about 5 cm cranial to the first long tail hairs (Figure 85-1). The site should be prepared aseptically. Administration of 2 to 3 mL of 2% lidocaine subcutaneously using a 25-gauge needle helps decrease the response of the horse to placement of the needle for epidural injection. An 18- or 20-gauge, 6.35-cm spinal needle with stylet is recommended for epidural injection in horses, although many clinicians use a standard 18-gauge needle. The bevel of a spinal needle is not as sharp as that of a standard needle and the bevel angle is less acute. This design makes it easier to identify penetration through the interarcuate ligament and the subsequent loss of resistance as the epidural space is entered. The needle is inserted at a 30- to 60-degree angle to horizontal, with the tip pointed cranioventrally, and is advanced until it contacts the floor of the vertebral canal (Figure 85-2). The depth of insertion is 3 to 6 cm,

Fig. 85-1 • The first coccygeal interspace between the first and second coccygeal vertebrae is identified while the clinician raises and lowers the tail and palpates for the articulation between these two vertebrae. This space is just caudal to the most angular portion of the bend of the tail.

depending on the size of the horse and the angle of the needle. The needle placement can be tested by attempting to inject 2 to 3 mL of air or solution in a 3-mL syringe. Resistance to injection should be little or absent. Appropriate epidural injection of local anesthetic solution and xylazine often is confirmed when anal tone decreases and the tail relaxes, but because the drugs most commonly used for epidural analgesia of the hindlimb (morphine, detomidine) have little or no effect on motor nerves, these responses will be absent.

EPIDURAL CATHETER PLACEMENT

The site for insertion of an epidural catheter is the same as for a single epidural injection. Placement of the catheter requires the use of a needle with a curved point (Tuohy, Becton, Dickinson, Franklin Lakes, New Jersey, United States) that will direct the catheter cranially, along the floor of the vertebral canal (Figure 85-3). The epidural catheter is made of polyamide (nylon) or Teflon, with a closed or open end, and it can be purchased with a wire stylet if desired. I use an 18-gauge, 8.89-cm Tuohy needle and a 20-gauge, 100-cm radiodense, polyamide catheter with a closed tip (bullet tip) without a stylet (Figure 85-4). Epidural catheters have marks every centimeter and multiple marks at 10, 15, and 20 cm from the end. Before needle and catheter placement, slide the catheter inside the needle and note the distance from the tip of the needle to the hub on the catheter. The clinician then should determine which mark on the catheter will be at the hub of the needle once the catheter has been advanced to the desired position.

As with the single epidural injections, strict attention should be paid to aseptic technique, and sterile gloves must be worn. Lidocaine is injected into the subcutaneous tissues at the desired site. A small incision is made through the skin with a No. 11 scalpel, because the Tuohy needle has a blunt tip. Once the needle has been positioned, the bevel should be directed cranially (the notch on the hub of the needle should face cranially). The catheter is threaded

Fig. 85-2 • A, The needle is inserted at a 30- to 60-degree angle to horizontal and is advanced until it contacts the floor of the vertebral canal. **B,** Sagittal view of the sacral vertebrae and placement of the needle within the epidural space. Fig. 85-3 • Curved point of a Tuohy needle.

through the needle and along the floor of the vertebral canal (Figure 85-5). Provided the needle is positioned in the epidural space, the advancing catheter receives little resistance. If the tip of the needle is angled incorrectly, the catheter tends to bump up against the vertebrae and will not advance. If this occurs, the needle is withdrawn 1 to 2 mm and the catheter is rotated slightly as it is advanced. It is critical that once the catheter has advanced any distance outside of the needle, it never be withdrawn back into the needle. This may result in cutting or shearing off of the catheter. The catheter is advanced 5 to 10 cm past the tip of the needle, and the tip is positioned in the mid-sacral region. Once the catheter has been positioned, the needle is carefully withdrawn over the catheter and

Fig. 85-4 • Tuohy needle and epidural catheter.

removed (Figure 85-6). Most epidural catheters intended for human use are very long to facilitate positioning of the injection port in a convenient place on the body. I usually cut the catheter with a scalpel (scissors tend to crush the catheter), leaving about 10 cm of the catheter to secure to

Fig. 85-5 • The epidural catheter is threaded through the needle and along the floor of the vertebral canal. If the catheter will not advance, the needle is withdrawn 1 to 2 mm, and the tip of the needle is angled up slightly.

Fig. 85-7 • The catheter or syringe adapter is attached, and an injection cap is secured to the adapter. A portion of tape is secured to the catheter at the point of insertion and then sutured to the skin.

Fig. 85-6 • Once the catheter is in place, the needle is carefully withdrawn over the catheter and removed.

the horse. The catheter or syringe adapter is attached, and an injection cap is secured to the adapter. A portion of tape is secured to the catheter at the point of insertion and then sutured to the skin (Figure 85-7). The syringe adapter also should be sutured to the skin, making sure tension will be minimal on the catheter during any movement of the horse. The catheter and injection cap then are covered with a sheer, adhesive dressing. Each injection into the catheter is made through the catheter cap after thoroughly cleaning it with alcohol, while wearing sterile gloves. It is critical that the catheter system remains sterile. A bacterial filter can be inserted between the syringe adapter and the catheter cap as an added precaution. The catheter site should be examined daily for signs of inflammation or infection, which would necessitate removing the catheter and submitting the tip for culture. With diligent aseptic

technique and catheter care, I have kept catheters in place for 2 weeks in horses, and some researchers have reported epidural catheters being maintained for 5 weeks in research horses.⁹

DRUG SELECTION

Epidural Opioids

The primary advantage of epidural administration of an opioid is the intense and prolonged, segmental (localized) analgesia achieved without either sedation or the possible excitement that may accompany the parenteral administration of an opioid. Unlike epidural local anesthetic solutions or xylazine, epidural opioids do not affect neuromuscular function or the sympathetic nerves.

The analgesia obtained with epidural opioids is primarily from the effect of the opioid within the spinal cord rather than from a supraspinal location. Opioids bind to presynaptic receptors of the afferent nerve terminals in the dorsal horn and inhibit the release of excitatory neurotransmitters such as glutamate and substance P. Opioids also act postsynaptically to inhibit transmission of impulses in ascending tracts. Evidence also shows that opioids enhance the effects of descending inhibitory pathways on the processing of pain within the dorsal horn.¹⁰

The onset and duration of action of epidural opioids vary greatly among drugs. The time to onset of analgesia reflects the time required for a drug to diffuse from the epidural space, across the meninges, into the spinal fluid, and ultimately into the spinal cord. Physicochemical properties of the drug, such as molecular weight, molecular shape, degree of ionization, and particularly lipid solubility influence the diffusion across the meninges.^{3,11} The more lipid-soluble drugs, such as fentanyl and butorphanol, have a rapid onset but a shorter duration of action, whereas the more water-soluble drug, morphine, has a delayed onset and a very long duration of action (Table 85-1).³ This delay in onset of analgesia with morphine can be particularly long in horses, and the drug may not reach peak effect

TABLE 85-1

<i>Characteristics of Analgesia and Side-Effects after Epidural Administration of Various Drugs</i>						
DRUG	DOSE (mg/kg)	ANALGESIA		SEDATION	ATAXIA	COMMENTS
		ONSET (min)	DURATION			
Morphine	0.1	150-180	12-18 hr	Minimal	No	Onset time for peak analgesia may be up to 6 hours
Butorphanol	0.04	?	2.5-3 hr	No	No	Degree of analgesia may be inadequate
Tramadol	1.0	30	6-12	No	No	
Xylazine	—	—	—	—	Marked	Not suitable for hindlimb analgesia
Detomidine	0.05	10-25	2-3 hr	Moderate	Mild	Decreased heart rate, blood pressure, and respiratory rate
Ketamine	1-2	5-10	30-75 min	Mild	Mild	Ataxia only at higher doses
Detomidine and morphine	0.03 and 0.1-0.2	10-25	12-18 hr	Moderate	Mild	Decreased heart rate, blood pressure, and respiratory rate

for several hours.¹² The more water-soluble opioids also tend to have greater degree of cranial diffusion within the CSF.²

Morphine remains the opioid of choice even though numerous other opioids have been evaluated for epidural analgesia in horses (see Table 85-1).^{5-7,13-15} Fentanyl has a faster onset of action but a considerably shorter duration of action (4 to 6 hours). Butorphanol provides inadequate analgesia. Analgesia after epidural administration of hydromorphone and methadone has been described in research horses.¹⁵ The onset of analgesia is more rapid than with morphine, and the duration of analgesia in the lumbar and sacral regions is approximately 4 hours. There may be benefit to using a drug with a more rapid onset, particularly in horses with an epidural catheter, which can facilitate more frequent administration. The utility of these drugs in horses with hindlimb pain remains to be evaluated.

I use preservative-free morphine (Abbott Laboratories, North Chicago, Illinois, United States) that is intended for epidural use at a dose of 0.1 mg/kg. The disadvantage of this preparation is the volume required. There are parenteral preparations of morphine that have been used for epidural administration in horses in an attempt to lower the cost, but some of these may contain substances such as phenol or formaldehyde, which may be neurotoxic. A preparation of morphine (25 mg/mL) with sodium bisulfite as an antioxidant (morphine sulfate, Hospira, Lake Forest, Illinois, United States) has been used in the horse epidurally, but the dose to be administered should be diluted in 20 mL of sterile saline solution. Epidural morphine has been used at a dose of up to 0.2 mg/kg combined with epidural detomidine.^{16,17} The higher dose may potentially speed the onset of action and extend the drug's duration, but it may increase the incidence of side effects.

Potential side effects include respiratory depression, pruritus,¹⁸ and urinary retention. These are rarely seen in horses and can be treated with naloxone (0.005 to 0.01 mg/kg). I have experience with a horse that developed substantial central nervous system effects after administration of morphine (0.2 mg/kg in 50 mL of saline solution), resulting in collapse, tachypnea, muscle rigidity, and hypoxemia. The horse was treated with naloxone (0.01 mg/kg), furosemide (2 mg/kg), diazepam (0.01 mg/kg), and a neuromuscular blocker to facilitate positive-pressure ventilation

after intubation and anesthesia with isoflurane. The horse recovered.

Epidural α_2 -Adrenergic Agonists

Epidural administration of an α_2 -adrenergic agonist can induce profound analgesia mediated by α_2 -adrenergic receptors in the spinal cord.¹⁹ The exact mechanism for the analgesia is not known. However, the α_2 -adrenergic agonists traditionally were thought to induce analgesia by mimicking action of norepinephrine released from descending noradrenergic inhibitory pathways.²⁰ Additional proposed mechanisms of action include modulation of pain via serotonergic and adenosinergic pathways, inhibition of the release of substance P, and effects on opiate receptors.^{21,22}

Xylazine, an α_1 - and α_2 -receptor agonist, is commonly used to induce analgesia of the perineal area of horses.²³ However, xylazine is not suitable for severe hindlimb lameness because of its effects on somatic motor innervation.⁸ Doses that exceed 0.25 mg/kg can cause substantial ataxia and have the potential to cause temporary hindlimb paralysis. Detomidine is a more selective α_2 -adrenergic agonist that primarily affects nerve fibers involved in pain transmission (C fibers and A delta fibers) and appears to have limited effect on somatic motor function at clinically used doses. Detomidine is therefore less likely to cause motor dysfunction and hindlimb paralysis, making it more appropriate for the treatment of horses with hindlimb pain. However, detomidine has a relatively short duration of action (see Table 85-1) and also has systemic effects, such as decreased blood pressure and heart and respiratory rates. Detomidine is best used with morphine and can provide additional analgesia. I use a combination of morphine (0.1 mg/kg) and detomidine (30 mcg/kg).

Other Drugs for Epidural Analgesia

Ketamine is an *N*-methyl-D-aspartate (NMDA) receptor antagonist that can be effective for pain resulting from central sensitization in the spinal cord and hyperalgesia caused by continuous nociceptive input from damaged tissue. Epidural ketamine has been administered to people and animals for treatment of acute and neuropathic pain with mixed results. Research horses given 1 mg of ketamine per kilogram epidurally had reduced postincisional pain

(flank incision) for several hours and demonstrated no signs of ataxia or sedation.²⁴ Epidural ketamine may be a suitable adjunct to other forms of analgesia, particularly in horses with inadequate analgesia from epidural morphine.

Tramadol is a centrally acting analgesic with effect on opiate, adrenergic, and serotonergic receptor systems. Tramadol (1.0 mg/kg) administered as a caudal epidural analgesic to horses induces analgesia, beginning at 20 minutes, that lasts approximately 6 hours in the sacral region and 5 hours in the lumbar and thoracic regions, with the analgesia in the more cranial regions being less intense.¹² The duration of this analgesia is slightly shorter than that of epidurally administered morphine, with a faster onset of action.

CLINICAL APPLICATIONS

Epidural analgesia can make a profound difference in the comfort and convalescence of horses and is frequently used in conjunction with other forms of analgesia, such as NSAIDs. Epidural analgesia is often used during the first stages of recovery from various disease processes, when the pain may be more intense, or immediately before or after surgical treatment of hindlimb injuries or disease. Procedures such as fracture repair and arthrodesis can cause pain intraoperatively and postoperatively. Preoperative administration of epidural opioids can decrease the concentration of inhalation anesthetic required, and some evidence shows that preoperative administration of epidural opioids is effective preemptive analgesia. Evidence also shows that effective preemptive analgesia can make postoperative pain management more successful. Because the onset of action of epidural morphine is prolonged in horses, administration of the drug 1 to 3 hours before induction of general anesthesia may be necessary to achieve the greatest effect postoperatively. A clinical impression exists that horses treated with epidural morphine have longer recovery times. My own impression is that recovery might be slightly prolonged, but not dangerously so, and that the horses are far more comfortable in the immediate postoperative period. Epidural administration of morphine provides analgesia that is far superior to what can be achieved with NSAIDs and parenterally administered opioid agonist-antagonists, such as butorphanol, without substantial systemic effects.

Horses with trauma to a hindlimb that require long-term therapy may benefit from the placement of an epidural catheter. I have left catheters in place for 1 to 2 weeks in some horses and as of yet have seen no complications attributable to the catheter. In some horses, however, the analgesia seems gradually to become less effective, despite increases in the dose and frequency of administration of epidural morphine. The addition of 30 mcg of epidural detomidine per kilogram every 6 to 8 hours has been beneficial in such horses. Ketamine,⁹ tramadol, or other α_2 -agonists, such as medetomidine, may have a role in treating horses with pain that is refractory to epidural morphine.

CONTRAINDICATIONS AND COMPLICATIONS

Complications associated with epidural analgesia can be grouped according to those caused by the drugs administered, those caused by the actual insertion of the needle or the catheter, and those secondary to the maintenance of

an epidural catheter. Complications reported with epidural morphine are rare in horses. Detomidine may cause cardiopulmonary depression, sedation, and ataxia. Careful assessment of the horse's cardiovascular status and appropriate dosage of the drug can minimize the risks associated with epidural detomidine.

Introduction of the needle or catheter into the epidural space potentially can cause trauma to the spinal nerve roots or the epidural venous sinus. Substantial bleeding in horses with normal clotting times and platelet numbers is unlikely. The possibility exists that if the tip of the needle is in the venous sinus, the drug administration will be intravenous as opposed to epidural and will not have the desired effect of prolonged, segmental analgesia. I have also, on one occasion, inadvertently catheterized the epidural venous sinus. If blood is obtained after aspiration of the catheter, the catheter (and needle if still in place) should be removed and a new catheter placed.

Potential complications secondary to the maintenance of an epidural catheter include localized soft tissue inflammation and, rarely, epidural abscess, vertebral osteomyelitis, and meningitis. The catheter site should be inspected daily for signs of infection or inflammation. Technical problems with the epidural catheter (dislodgement, kinking) are more likely to result in early removal of the catheter than other complications.²⁵

Possibly the most serious potential complication would be the inadvertent injection of an inappropriate substance or an overdose of the drug into the epidural catheter. The epidural catheter should be clearly marked as such, and all personnel working with that horse should be instructed in the care of the catheter and the amount and type of drugs that are administered through the catheter.

NOVEL ANALGESIC DRUGS AND ADJUNCTIVE THERAPIES

The transdermal route of drug administration can be used for opioid administration in horses. The transdermal therapeutic system for fentanyl administration is used in horses by applying patches to either the neck or the lateral aspect of the antebrachium.^{26,27} Two 10-mg patches (Duragesic 100 mcg/hr, Janssen Pharmaceutical, Titusville, New Jersey, United States) are generally used for adult horses. A pharmacokinetic study of transdermal fentanyl found that serum levels of fentanyl considered to be analgesic were present within 8 to 15 hours and were maintained for up to 32 hours. The application of fentanyl patches in conjunction with NSAIDs in horses with pain from soft tissue and orthopedic disease resulted in decreased overall pain scores, but improvement in the horses with orthopedic disease was minimal and lameness scores did not change.²⁷ My experience with transdermal fentanyl in horses is similar. Clinical signs in horses with soft tissue injuries and abdominal pain may improve, but the analgesic benefit in horses with acute or substantial orthopedic pain is questionable.

Subanesthetic doses of intravenous ketamine have been used to provide analgesia in small animals and people. A constant rate infusion of as low as 0.4 mg/kg/hr in horses results in plasma levels of ketamine above those needed to provide analgesia in people, and doses of 1.2 mg/kg/hr

were analgesic in research horses with minimal changes in behavior.^{28,29} The efficacy of low-dose constant infusions of ketamine in painful horses is yet to be determined. I have used low-dose ketamine (0.3 mg/kg bolus and 1 mg/kg/hr) in a limited number of horses that were in pain despite opioid therapy, and horses appeared to show modest to marked improvement.

Other adjunctive analgesic agents used in veterinary medicine include the anticonvulsant gabapentin (Neurontin, Pfizer, New York, United States). The proposed analgesic mechanism is mediated by binding to a presynaptic voltage-gated calcium channel in the dorsal root ganglia and spinal cord, which inhibits calcium influx and subsequent release of excitatory neurotransmitters.³⁰ Gabapentin has become an established therapy in some types of

neuropathic pain, and its use for acute, perioperative pain is being investigated. Limited pharmacokinetic data in horses have revealed maximal plasma levels that were lower than those in people and dogs given a similar dose.³¹ There is a single case report of a mare with femoral neuropathy that was given 2.5 mg/kg of gabapentin every 8 hours. The authors concluded that gabapentin appeared to be an effective treatment for neuropathic pain in that horse.³² My only experience with gabapentin is in dogs with severe neuropathic or chronic pain, with responses varying from excellent to poor. One of the Editors (SJD) has treated several horses with suspected neuropathic pain with complete remission of clinical signs; however, horses with severe, chronic pain associated with laminitis have shown only limited improvement.

Chapter 86

Bandaging, Splinting, and Casting

Alan J. Ruggles and Sue J. Dyson

Indications for bandaging and cast application include protection of limbs during transport and performance, reduction of soft tissue swelling, protection of surgical wounds, management of skin defects and granulation tissue, protection of surgical implants, management of fractures, and first aid before transport of injured horses. This chapter discusses methods of bandage, splint, and cast application and the acute management of a horse with a suspected fracture or soft tissue injury.

STABLE AND TRAVELING BANDAGES

Bandages used routinely as stable bandages or for transport consist of a padded, quilted, fleece, or an interwoven sheet of cotton as a protective layer, held in place by a flannel wrap or commercially available bandage material. Horses that continually wear stable bandages tend to develop ridges in the hair coat, and this should be noted at a pre-purchase examination. Proper bandaging prevents limbs from filling in a stabled horse and helps to prevent injury during transport. The coronary band region is particularly vulnerable during transport, loading, and unloading, and the bandage ideally should extend to cover this area. Alternatively, overreach (bell) boots should be used. Improper bandage application or management can cause the development of white hairs, transient edema, and structural damage to soft tissue structures and, under severe circumstances, pressure necrosis. An excessively tight bandage can result in severe tissue necrosis within 24 hours, resulting in full-thickness skin loss and damage to the underlying soft tissues. The midmetacarpal region seems to be

particularly vulnerable. Alternatively, commercially available boots can be used for transport, the best of which extend from proximal to the dorsal aspect of the carpus, or the plantar aspect of the tarsus, to cover the coronary band. The use of exercise bandages and boots for protection and support is discussed in Chapter 37.

BANDAGING WOUNDS

The principles of bandages used to protect wounds are to absorb exudate, reduce soft tissue swelling, and provide an environment conducive to wound healing. Each wound has its own characteristics that make a specific type of bandage, or even the absence of a bandage, ideal. All bandages prevent or reduce edema by providing pressure. A bandage can immobilize a region to a certain extent; the degree of immobilization depends on the type of material used and the manner of its application.

Surgical wounds are generally created under ideal conditions, and proper apposition of the skin edges occurs during suturing. Protection is provided by a nonadherent, porous dressing (Telfa, Kendall Co., Mansfield, Massachusetts, United States) over the wound. The dressing is held in place with a sterile gauze roll (Conform, Kendall Co.), and then a cotton combine roll 45 cm wide (for the lower limb only), or alternatively a soft conforming bandage (Soffban, Smith and Nephew, Hull, North Humberside, United Kingdom). The gauze is held in place with an elastic conforming bandage (Vet-Wrap, 3M Animal Care Products, St Paul, Minnesota, United States; Elastikon, Johnson and Johnson, Arlington, Texas, United States). These dressings are changed every 2 to 3 days, or earlier as needed, until suture removal. In some circumstances bandaging may be prolonged to reduce postoperative swelling and improve cosmetic results. If a full-limb bandage is placed to extend above the carpus or tarsus, an additional bandage 40 cm wide is applied above the first bandage. A layer of gauze is used over the combine and cotton, and an elastic conforming bandage (Elastikon) is then applied. Finally, additional elastic tape is used to secure the top of the bandage to the skin. These types of bandages are used postoperatively for most horses undergoing orthopedic procedures, such as arthroscopy or splint removal, and

for most horses with limb wounds, assuming the limb is stable.

In a forelimb the area of the bandage over the accessory carpal bone is incised with a scalpel blade to prevent rub sores from developing. In a hindlimb the point of the hock can be covered by the bandage if duration of bandaging is anticipated to be less than 1 week. If prolonged bandaging is required, the point of the hock should not be covered, to prevent rub sores and potential development of white hairs.

Roll cotton (cotton wool) rather than combine roll may be used for the proximal portion of carpal bandages, because it stays in position best. Roll cotton is particularly useful for reducing soft tissue swelling after desmotomy of the accessory ligament of the superficial digital flexor tendon. A nonadherent layer and conforming gauze are covered by elastic adhesive bandaging tape before application of a full-limb padded bandage. This provides protection of the wound from the environment and prevents hematoma and seroma formation. Care must be taken to avoid excessive tension being applied to the elastic adhesive tape to prevent pressure necrosis.

Pressage Bandages

Pressage bandages (S.C. Meades, Cardiff, Wales) are commercially produced elasticized bandages designed specifically for the carpus and hock and available in three sizes. They provide an excellent method of securing a light bandage in place and providing pressure, with a minimal risk of pressure sores, and are used routinely by one author (SJD). Two turns of an elastic conforming bandage over the proximal extent of the Pressage bandage and application of a stable bandage in the more distal part of the limb help to keep the Pressage bandage from slipping.

Ether Bandages

Ether bandages are used to cover surgical incisions, but they do not provide any compression to the incision. For the ether bandage to stay, the area to which it is applied must be clipped or preferably shaved. Cleansing of the skin with surgical scrub, followed by alcohol rinsing, provides the best environment on which to apply this bandage. Strips of adhesive elastic tape approximately 15 cm in length are cut, and ether is applied to the adhesive side of the bandage tape. The ether-soaked bandage is then applied over gauze sponges and held in place while the ether evaporates and the adhesive dries to the skin and elastic tape. Three or four strips of elastic tape typically are used. Ether bandages are extremely adherent and very useful to protect surgical wounds made for stifle arthroscopy, bone grafts from the tuber coxae, and plate fixation of the olecranon (Figure 86-1). Because of the explosive nature of ether, proper precautions should be followed in its use and storage. Commercially available Primapore (Smith and Nephew) or Coverderm (DeRoyal, Powell, Tennessee, United States) dressings provide a simpler alternative but are less adherent.

Stent Bandages

Stent bandages are towels or gauze rolls that are sutured over wounds to protect the wound from the environment or to relieve tension at the sutured site. A sterile hand towel or gauze sponges, rolled like a cigar to the proper width of

Fig. 86-1 • Application of an ether bandage over an incision for repair of a fractured olecranon in a yearling.

the wound, are sutured over the wound with No. 2 or larger suture. A cruciate pattern is usually used. Stent bandages are used after shoulder arthrotomy, after olecranon or femur fracture repair, to cover wounds over the point of the hock, and for other incision sites unsuitable for bandaging. If the stent is to be changed routinely, then loop sutures are placed on both sides of the incision, and umbilical tape can be used as suture to hold the bandage in place between changes.

Wet-to-Dry Bandages

Wet-to-dry bandages are used to absorb exudates and to provide an environment conducive to wound healing, particularly in the proliferative phase of wound healing. After cleansing of the wound, sterile sponges moistened with saline solution are applied to the wound and held in place with normal bandaging techniques. The bandage is changed daily, or as needed, and the process can be repeated as often as necessary until a granulation bed has formed.

With any wound there is a combination of dressings, bandaging, immobilization, and systemic therapy that is appropriate. The management changes as the wound heals, and sometimes alternative strategies need to be adapted. Careful attention to the progress of the wound and understanding of wound healing principles optimize outcome.

Foot Poultice

If a subsolar abscess is suspected, applying a poultice may be necessary, along with foot soaks, to soften the sole to permit drainage and to draw the abscess. A commercial poultice such as Animalintex (3M Animal Care Products; Robinson Animal Healthcare, Chesterfield, United Kingdom) is the simplest to use. A half piece is usually adequate. It should be thoroughly soaked in hot water and partially squeezed out before being applied to the sole of the foot. The poultice is covered by a thick layer of cotton

wool, and then conforming bandage is wrapped around the foot to hold the poultice in position. To keep the moisture in, the foot can be placed in a used intravenous fluid bag, which is then covered by duct tape to provide a durable bandage.

Robert Jones Bandage

A Robert Jones bandage is used when additional support or compression is required. The bandage is particularly useful for immobilizing the limb of a horse with a suspected fracture for transport or for recovery from general anesthesia after fracture or wound repair—for example, after lag screw repair of a simple proximal phalangeal fracture or a condylar fracture of the third metacarpal bone. The Robert Jones bandage also can provide limb support if the suspensory apparatus is disrupted, can control severe posttraumatic limb edema, and can provide substantial pain relief to a horse with a severely injured superficial digital flexor tendon. This bandage has a multilayered construction. Compared with a single-layered bandage, a Robert Jones bandage compresses air-filled cotton wool layers to increase rigidity and spread pressure evenly. A half-limb bandage requires four to five rolls of cotton wool, eight to 10 conforming bandages, and three to four rolls of elastic adhesive tape. A full-limb bandage needs twice as much. For a half-limb bandage for a forelimb, the cotton wool should be applied snugly from the foot to the distal aspect of the carpus, incorporating the foot. The first layer, using one and a half to two rolls of cotton wool, should be 2 to 3 cm thick. This layer is then compressed using several conforming bandages at least 15 cm wide. Each bandage is applied using fairly firm, constant pressure to compress the cotton wool evenly. Filler layers of cotton wool usually are needed at the top and bottom of the bandage to create a uniform cylinder. A length of cotton wool is folded in half and placed around the top and bottom of the bandage as a filler layer. Another 2- to 3-cm layer of cotton wool is then applied and is compressed using a conforming bandage. At least three layers are constructed to create a thickness of 6 to 8 cm. The entire length of the bandage is then covered with elasticized tape, which should extend the entire length of the bandage and above and below it, to prevent dirt and bedding material from getting into the bandage. The end of one roll of elasticized bandage and the beginning of the next should overlap to prevent unraveling of the bandage. The end of the last roll is covered by zinc oxide tape. A full-limb bandage is applied similarly. In a forelimb the bandage should extend the entire length of the limb, incorporating the elbow; in a hindlimb the bandage should extend to the proximal aspect of the tibia.

Splinting

Splints should be used to support unstable fractures, when disruption of the suspensory apparatus is suspected, and when a full-limb Robert Jones bandage is used to provide additional support. Proper splinting helps protect bone from further trauma, prevents further soft tissue damage, and may also increase the horse's comfort. Wood or plastic guttering (diameter about 112 mm), cut in half to give a U shape, can be used. Polyvinyl chloride (PVC) piping is lightweight, inexpensive, and strong, but wood is generally more suitable for lateral splints. The length of the splint

depends on the size of the horse and the position of the injury. It is critical that the splints be adequately padded, especially at the top and bottom, to avoid rub sores. A gutter splint can be padded throughout its entire length with cotton wool. Wooden splints should be padded at the top and bottom. The splint should be covered with elastic adhesive tape proximally and distally to prevent it from becoming damaged and developing rough, sharp edges. A splint generally is applied over the dorsum to immobilize the distal aspect of the limb. If a transverse or oblique fracture is suspected, or if support of the suspensory apparatus is lost, the limb should be splinted to align the dorsal cortices of the third metacarpal bone and phalanges to eliminate the bending forces of the metacarpophalangeal joint. An assistant is needed to hold the limb off the ground, supporting it under the antebrachium. One layer of the Robert Jones bandage is applied, and then the splint is strapped to the dorsum of the limb before application of the second layer of the Robert Jones bandage. The splint should be well reinforced at the toe. If a sagittal plane fracture or subluxation or luxation of a joint is suspected, supporting the limb in its normal position is preferable. The splint then can be applied over the full thickness of the Robert Jones bandage. To immobilize the carpal region, or if a fracture in the midmetacarpal region is suspected, caudal and lateral splints are used, extending to the elbow (Figure 86-2). With a fracture of the midradius or proximal aspect of the radius, abduction of the limb is prevented by placement of a lateral splint extending from the ground to the middle of the scapula. The top of the splint must be well padded to prevent rub sores. With a fracture of the

Fig. 86-2 • Full-limb forelimb bandage with lateral and caudal polyvinylchloride splints for an unstable diaphyseal third metacarpal bone fracture in a foal.

ulna and loss of triceps function, it is best to fix the carpus in extension by using a caudal splint extending from the ground to the proximal aspect of the olecranon. In some horses with olecranon fracture this type of splinting makes it more difficult to ambulate, and in those horses this splinting is not used initially. Similar principles apply in a hindlimb. Not all horses tolerate immobilization of a hindlimb, and the clinician must be prepared for the horse to react adversely when it first moves. For horses with fractures of the distal metatarsal region and distally, the limb is held above the hock by an assistant while the Robert Jones bandage and dorsal splint are applied. With a suspected fracture of the midmetatarsal and proximal metatarsal regions, the Robert Jones bandage should be applied with the limb bearing weight, and plantar and lateral splints are applied. The plantar splint should extend up to the proximal aspect of the calcaneus, to fix the tarsus to the distal limb fracture. Wood splints are stronger than gutter splints. Splinting of the hock and distal tibial regions aims to counteract the destabilizing effect of flexion of the stifle through the reciprocal apparatus. To immobilize the hock, a lateral splint is contoured to the angle of the hock by heating PVC gutter pipe over a flame, or by using a 12-mm steel rod that can be shaped by hand but is strong enough to provide support. The splint should extend to the proximal aspect of the tibia. An additional contoured splint can also be placed distal to the stifle and proximal to the fetlock on the plantar (caudal) side.

Several commercial splints are available that are particularly useful in an emergency situation, being easy to apply and rapidly providing pain relief by immobilization of the limb. These include the Kimzey Leg Saver Splint (Figure 86-3) (Kimzey, Woodland, California, United States) and the Monkey Splint (Kruuse, North Yorks, United Kingdom). They are all designed to align the dorsal cortices of the distal limb bones and are appropriate for fractures

Fig. 86-3 • Kimzey Leg Saver Splint used for first aid treatment of traumatic disruption of the suspensory apparatus.

and luxations distal to the distal third of the metacarpal or metatarsal regions or suspensory apparatus breakdown. The Kimzey Splint also has an extension that reaches to the proximal aspect of the antebrachium and is suitable for use in horses with fractures up to the carpus.

TRANSPORT OF AN INJURED HORSE

With appropriate immobilization of a limb, a horse with a suspected fracture or major soft tissue injury can be safely transported long distances to a clinic with suitable diagnostic and surgical facilities and a skilled surgeon. Ideally the horse should be transported in a low-loading vehicle. Alternatively the horse should be loaded via a loading ramp, or with the ramp of the vehicle placed on a slope, so that the incline up the ramp into the vehicle is shallow. Ideally a horse with a forelimb injury should travel facing backward so that major load is placed on the hindlimbs when the vehicle decelerates. A horse with a hindlimb injury should travel facing forward. Appropriate but not excessive sedation may be required for transport of a fractious horse. A clinic expecting to receive such horses also should have a loading ramp to minimize the incline down which the horse has to walk when unloaded.

CAST BANDAGE

Cast bandages are a combination of a standard bandage, casting tape, and splint material (typically PVC). Clinical indications for this technique include management of wounds over the carpus, including transverse lacerations or hygroma resection. After placement of a standard bandage, two layers of cast material are placed over the bandage in the area to be splinted. The splint is then applied and held in place while at least two additional layers of casting tape are applied. In 2 to 3 days the cast material is split to create a bivalve to allow access to the surgical site. The cast can then be reapplied to provide immobilization.

CAST APPLICATION

Indications for cast application include after fracture repair or suturing of lacerated tendons or for wound management. Commonly used materials include plaster of Paris, resin-augmented plaster, and fiberglass. Fiberglass casting tape consists of knitted fiberglass fabric impregnated with polyurethane resin and is preferred and used most commonly because of its greater strength, lighter weight, and quicker setting times, despite increased cost. Full-limb (up to elbow or stifle) and half-limb (up to carpus or tarsus) casts can be applied. Full-limb casts are not well tolerated by all horses, and the horse's temperament should be assessed carefully, particularly before application of a full hindlimb cast. Casts are changed as needed because of rub sores, suture removal, inspection of the limb, and/or breaking or buckling of the cast, usually within 4 weeks after placement. In some circumstances a cast can be left on for up to 6 to 8 weeks; however, the risks of cast rubs increase the longer the cast is left on the horse. The use of hydrocolloidal dressings (Tegaderm, 3M Health Care, St Paul, Minnesota, United States) directly over pressure points is useful

Fig. 86-4 • Procel Cast Liner being applied before fiberglass casting tape.

to prevent and/or treat cast rubs. The placement of a cast effectively lengthens the injured limb. Placement of a shoe equalizes the limb lengths and helps to prevent excessive weight bearing in the unaffected limb. Support of the contralateral foot with a wedge cuff shoe (Nanric Ultimate, Nanric, Lawrenceburg, Kentucky, United States) and sole support (Advanced Cushion Support, Nanric) is recommended if a horse is to be maintained in a cast for a long time.

Casts can be applied in a conscious, sedated horse but are commonly applied with the horse under general anesthesia, after internal fixation or wound repair. The limb should be clean and dry before cast application. Sterile dressings are applied over the surgical site, and a thin layer of nonbinding material such as cotton cast padding should be used to secure the wound dressings. A double layer of sterile stockinette is applied over the limb and extends above the proximal extent of the cast. Four to 5 cm of orthopedic felt is placed at the proximal extent of the cast. Wider felt is used for full-limb casts. In addition, orthopedic felt with the centers cut out can be placed over bony prominences, such as the styloid processes or accessory carpal bone in full-limb casts, to avoid rubs. The felt is secured with adhesive tape. Wire can be placed through holes made in the hoof wall near the toe and secured to a twitch handle to provide a means for an assistant to hold the limb and maintain the proper angle of the digit. In general, the hoof is placed at or near a weight-bearing position. Alternatively, the hoof can be extended to a lesser extent by manual pressure at the toe. Cast padding is applied and overlapped about 50%. The use of 3M Custom Support Foam (3M Healthcare), which has a polyurethane resin-impregnated cast padding, is helpful in reducing cast rubs. Another cast padding product is Procel Cast Liner (W.L. Gore and Associates, Flagstaff, Arizona, United States), which remains dry and allows the skin to remain dry through evaporation (Figure 86-4). It is important not to use too much cast padding, because the cast will compress it and the cast will become loose, predisposing

the horse to rub sores. Casting tape (3M Scotchcast, 3M Healthcare; 10 to 12 cm wide) is applied, beginning on the orthopedic felt at the top of the cast. The material is spiraled down the limb, taking care not to apply it too tightly, while avoiding wrinkles. Because the limb is not a perfect cylinder, wrinkles tend to develop in areas where contouring is necessary. Tension across the width of the casting tape eliminates potential folds or wrinkles. The next roll of casting tape begins where the first leaves off. At least five rolls of casting tape are used on the limb to construct a half-limb cast, and sometimes one or two additional rolls. When this is complete, more casting tape should be applied at the fetlock and distally, because this is the most common site of breakage. If the distal limb is extended using wires through the hoof wall, the toe region is not cast until the rest of the limb is finished and the twitch handle is no longer necessary. The wire and twitch handle are removed and the foot is covered with one to two rolls of casting tape. If a heel wedge is required, folded casting tape or a wood wedge can be incorporated in the casting tape applied to the hoof. Polymethylmethacrylate (Technovit, Jorgenson Laboratories, Loveland, Colorado, United States) is applied to the bottom of the cast, especially if the cast is to remain more than 2 weeks, to prevent wearing through of the casting tape.

For application of a cast in a standing horse the same protocol is followed, except a 2.5- to 5-cm block is placed under the horse's hoof, so that the heel is left hanging slightly over the edge of the block, and the cast is applied. After the limb has been cast, the limb is lifted and casting tape and polymethylmethacrylate are applied to the hoof. When standing casts are applied for first aid treatment of unstable fractures, a dorsal splint can be incorporated to maintain the bony column in a straight line. Foot casts are useful in managing heel bulb lacerations and in the prevention of support limb laminitis.

Potential cast complications include rub sores and cast breakage. Rub sores can occur over any bony prominence or any area where cast folds or fingerprints are present. Common sites for cast rubs include the proximal dorsal metacarpal and metatarsal regions, proximal sesamoid bones, and heel bulbs in half-limb casts; and the elbow, distal aspect of the radius, accessory carpal bone, stifle, and point of the hock in full-limb casts. Increased lameness, fever, drainage, heat, foul odor, and swelling proximal to the cast are signs of cast rubs. Rub sores are common complications of cast application and usually are managed easily by cast change or removal. Failure to recognize rub sores can lead to serious problems, such as large wound defects, infections of synovial structures, or laminitis in the supporting limb. Proper application and careful monitoring of cast is essential to prevent serious rub sores.

Transfixation Pin Casts

The use of transfixation pin casts is discussed in Chapter 87.

Chapter 87

External Skeletal Fixation

David M. Nunamaker

HISTORY AND DEVELOPMENT

Using external skeletal fixation to treat fractures in the horse has only recently received some enthusiasm from equine surgeons. Although external skeletal fixation of fractures works well in small animals and has undergone periods of enthusiastic use, these same devices do not withstand the loads of weight bearing in an adult horse and therefore are not versatile enough to meet the needs of equine surgeons. Using transfixation pins in plaster, transfixation pins in fiberglass casts, or an external skeletal fixation device, has allowed salvage of some horses with difficult fractures that could not have been saved using internal fixation (Figure 87-1).

The incorporation of a walking bar cast, with transfixation pins placed in the bone above the fracture, was described in 1991 to manage fractures in horses and ponies.¹ An overall success rate of 57% was reported for a variety of fractures in 35 horses and 21 ponies. The authors suggested that using transfixation pins incorporated into the cast material may help prevent fracture through these pin sites. Major complications of the technique included infection in nine horses or ponies, fracture through the bone or pin sites in six horses or ponies, and loss of circulation to the distal phalanx in two horses or ponies. Complications in the remaining seven nonsurvivors were not reported.¹ Using *in vitro* tests, McClure and colleagues^{2,3} suggested that a walking bar was not necessary when using fiberglass casts and that divergent transfixation pins may be helpful in preventing fracture through the pin tract sites.

Although transfixation pins have been used successfully in fiberglass casts, this technique represents a compromise compared with classical external skeletal fixation. In horses managed with transfixation pin casts, wounds, skin, and pin sites must be covered in the cast, and at the time of every cast change, fractures are remobilized, allowing fracture collapse or shortening of the limb segment. In addition, pin loosening, pin breakage, and local infection at pin sites are common sequelae of this form of transfixation pinning, often necessitating pin replacement through new pinholes. The use of tapered-sleeve pins (TSPs) in a fiberglass cast has been reported.⁴ This technique increases the strength and durability of the pin and appears superior to use of unprotected pins alone, and fewer pins may be needed in the pin cast.⁴ This technique is used as an intermediate step after removal of the newly designed TSP external skeletal fixation device (ESFD) (see later).

The development of an equine ESFD in our laboratory had its origins before the first horse was treated in 1981, and we described the design and development of that device in the first 15 horses in 1986.⁵ The ESFD was designed to allow immediate full weight bearing in an adult horse

and was used in horses with severely comminuted fractures of the distal aspect of the limb, in which internal fixation was not indicated or was impossible to carry out. A follow-up study including five additional horses along with further development of the device was published in 1992.⁶

Although the previous models of the ESFD proved the feasibility of using external skeletal pin transfixation in a frame device for immediate full weight bearing in an adult horse, there were substantial problems associated with the treatment itself. The original device used three unprotected 9.6-mm-diameter centrally threaded stainless steel pins loaded in bending within the intact bone (the third metacarpal bone [McIII]) above the fracture site, with two sidebars that connected the pins to a ground support through a base plate that was nailed to the horse's hoof, much like a shoe. This allowed the forces of weight bearing to bypass a comminuted fracture with support through the pins, sidebars, and base. Six (22%) of 27 horses in which the original device was used developed fractures of the McIII through one of the pin holes (usually the proximal pin hole while wearing the device) either when wearing the device or shortly after removal of the device. Problems associated with catastrophic failure of the McIII through a pin hole after device removal were controlled by removing the device while the horse was standing rather than subjecting horses to the rigors of recovery from general anesthesia. After this modification there were no further incidents of McIII fracture after device removal (used in 12 horses without incident).

In 2001 we described a radical change of design of the transfixation pins that was aimed at reducing the incidence of these McIII failures through the pin holes.⁷ Several horses treated with this new design as well as horses treated with the old design were among a larger group of 64 horses with comminuted proximal phalangeal fractures reported in 2004.⁸

Mechanics of External Skeletal Fixation

The normal loading regimen for a transfixation pin is in bending. This is similar to hanging a weight in the middle of a clothesline stretched between two poles. The weight of the object causes the clothesline to sag, which can be compared with bending of the transfixation pin when the horse's weight is transmitted down the bone through the pins to the sidebars. The amount of deflection in the pin is related to the load, the pin diameter, the pin material, the distance from the bone to the sidebar, and the cortex thickness. Pin stiffness is a function of the fourth power of its diameter, whereas pin deflection is proportional to the cube of the distance between the bone and the sidebars. These power relationships show that very small changes in pin diameter or distance to the sidebars make a large difference in the performance parameters of the device. Theoretically to prevent bending of the pin one should reduce the bone-sidebar distance to zero, and the pin diameter should approach infinity. Obviously these parameters are unacceptable in a clinical situation, in which skin and soft tissues represent a barrier to the zero distance, and large holes drilled into bone will decrease bone strength leading to failure, especially if the diameter of the hole is greater than 30% of the smallest cross-sectional diameter of the bone.⁴

Fig. 87-1 • Dorsopalmar (A), dorsolateral-palmaromedial oblique (B), and dorsomedial-palmarolateral oblique (C) preoperative radiographic images show a severely comminuted fracture of the proximal phalanx. The fracture was open and the horse was managed using a tapered sleeve pin external skeletal fixation device. D, Five years after fracture there is radiological evidence of healing of the proximal phalanx and fusion of the metacarpophalangeal joint, but healing was delayed by motion (see broken screws). The proximal interphalangeal joint fused spontaneously, as usually occurs when the original fracture enters this joint. To date this mare has successfully foaled five offspring.

Up to 90% of the magnitude of the total stress at the bone-pin interface is attributed to stresses generated by the bending moment.⁷ The highest stresses are seen on the surface of the bone at the pin junction, and because bone fails (breaks) at about 2% strain regardless of load, lowering the bone-pin stress should allow an increased load before failure. The solution for this problem was to load the pin uniformly in shear instead of bending to get a uniform load all along the pin as it passed through the bone.⁷ To accomplish this goal we used transcortical pins that slid into a tapered sleeve. The TSP ends are threaded and compress

the tapered sleeves against the bone when fasteners (nuts and lock washers) are used to provide tension in the pins. The pins are then biaxially loaded in tension via the nuts and in shear via the axial load on the bone (Figure 87-2).⁷

Although the device could be made in many sizes, it was sized for light horses, ranging from an adult Arabian to larger Warmblood crosses. It ideally fits Thoroughbred (TB) and Standardbred (STB) horses, in which the device has been used most frequently. Two 7.94-mm pins are incorporated into the tapered sleeve and attached through a welded collar steel tube system to the aluminum-magnesium

Fig. 87-2 • This drawing shows the concept of sleeves that slide over the transfixation pins to give protection from bending in the external skeletal fixation device. The large diameter of the sleeves and the proximity to the bone eliminate bending as a loading mode and ensure a more uniform loading on the pin in shear. This protects the outer bone cortex from the loads of a bending pin and allows the device to be loaded to about 10 times body weight before bone failure.

Fig. 87-3 • The present tapered sleeve pin external skeletal fixation device is shown. The device is assembled easily over the tapered sleeves using the footplate attached to the base.

base through an aluminum foot plate. The device is always applied with the horse under general anesthesia (Figure 87-3).

The TSP ESFD with all the tools to apply and remove it is commercially available (rane@magnolia-net.com,

Ron Nash Engineering, 977 Stephens Highway, Magnolia, Arkansas, United States).

PREOPERATIVE PLANNING, INDICATIONS, TIPS, AND LIMITATIONS

The TSP ESFD was designed to treat horses with catastrophic injuries of the distal limb. Indications include comminuted fractures of the proximal phalanx when no strut (intact piece of bone from the proximal to the distal articular surface) is available for use with internal fixation (see Chapter 35), comminuted fractures of the middle phalanx, fracture dislocations, or traumatic disruptions of the suspensory apparatus with massive soft tissue injury (see Chapters 36 and 104). Expanded use of the ESFD could be considered in horses with severe laminitis. In its present form the TSP ESFD is designed for use when the McIII or the third metatarsal bone (MtIII) is intact. The only other requirement is that the blood supply to the distal limb must be intact. In addition to applying the ESFD, it is sometimes helpful to insert bone screws, used in lag fashion through stab incisions, to hold large fragments together. This can be done under radiographic guidance, and these fixations do not need to resist weight-bearing forces, because the ESFD supports the entire weight of the horse. It is necessary that the hoof fits on the base plate of the device, and, if large, the hoof needs to be trimmed. This must be accomplished to allow the aluminum base plate to attach to the magnesium-alloy base using the three cap screws. A compression bandage (elastic bandage) is wrapped around the fractured bone before and during surgery to bring the bone fragments closer together and reduce swelling, which helps with reduction of badly comminuted fractures.

Abbreviated instructions for application of the TSP ESFD are included to show the simplicity of the system. The procedure is completed with the horse under general anesthesia. The only surgical requirement for application of the device is to drill two holes in the McIII, although additional internal fixation may be used when appropriate. The footplate is attached using a glue-on system (www.soundhorse.com). The limb is prepared for aseptic surgery. With the drill guide supplied, two 7.94-mm holes are drilled, one at the junction of the proximal and middle thirds and the other at the junction of the middle and distal thirds of the McIII from the lateral aspect. Holes are placed in the center of the bone and marrow cavity and perpendicular to the long axis of the bone. This is facilitated using the dual drill guide, which places the holes parallel and properly spaced. Next the 7.94-mm pins are inserted using the threaded cap to protect the threads. The sleeves over the pins are assembled on the medial and lateral sides and secured with nuts. The sleeve-skin junction is wrapped with a sterile bandage, and the rest of the assembly is performed using nonsterile technique. The side tubes are then assembled using ring connectors over the tapered sleeves on both sides of the limb. The base is slid into the distal ends of the tubes, and the base is fastened to the footplate using cap screws supplied. The reinforcing rods are then inserted into tubes on the medial and lateral sides, and electrical tape is placed around all the tubular junctions to prevent leakage. The fracture is reduced and stabilized by placing traction on the limb in a position that allows the tubes to be filled. The polymer (Conathane UC41, Cytec Industries, Olean, New

Fig. 87-4 • A tapered sleeve pin external skeletal fixation device is used to manage a horse with a comminuted fracture of the middle phalanx.

York, United States) is then mixed (2:1 by volume) and poured into the sidebars. The tubing is cooled, using cold saline solution if necessary, to prevent heating of the pins. Last, the now wet sterile wrap around the tapered sleeves is removed, and the ESFD is covered with a bandage. The horse is then recovered from general anesthesia. The current ESFD is shown being worn in [Figure 87-4](#).

The contralateral foot often has a shoe applied that elevates the limb so that the horse stands squarely. Without this elevated shoe the horse has a tendency to point the foot in the TSP ESFD while standing. It is important to keep the horse standing squarely on both limbs to help prevent laminitis from occurring in the supporting, non-injured limb.

POSTOPERATIVE CARE

After recovery from general anesthesia the horse is immediately fully weight bearing and usually comfortable on the limb. In fact, this is a major advantage of this type of fracture management. Skin care around the pin sites is important during the initial postoperative period and is done easily using antiseptic-soaked sponges. The TSP ESFD is checked for tightness using an appropriate deep socket wrench every few days. Pin loosening does not occur, because one has the ability to tighten the pins with the fastener nuts already in place, which is easily done and does not require sedation of the horse. Reducing pin loosening helps to diminish pin tract infections and allows the horse to remain fully weight bearing. Local antiseptic application at the pin sites may decrease severity of pin site infections. Some horses may be discharged from the hospital with the TSP ESFD in place. If the owner or trainer

can provide pin care, discharging the horse as soon as possible decreases the cost of hospitalization. The horse is returned to the hospital for removal of the TSP ESFD after 8 to 10 weeks. Although the device can be left on longer, substantial osteoporosis of the McIII or the MtIII below the lowest pin may be detrimental to the end result. Radiologically the fracture site may not appear healed (based on the observation of mature callus) at this time, because osteoid will have formed, but calcification of this soft callus will not yet have occurred without the stimulus of weight bearing. The TSP ESFD is removed in the standing, sedated horse, and a fiberglass cast is applied. Serial radiographic examinations are then performed until radiological evidence of fracture healing is visible. Spontaneous fusion of the proximal interphalangeal joint will occur in horses with comminuted fractures of the proximal phalanx. If arthrodesis of the metacarpophalangeal or metatarsophalangeal joint is necessary, additional internal fixation, usually screws alone, will be needed because spontaneous fusion rarely occurs (see [Figure 87-1](#)). Most horses with fractures of the proximal phalanx managed with the TSP ESFD need arthrodesis of the metacarpophalangeal or metatarsophalangeal joint to maintain comfort.

REMOVING THE EXTERNAL SKELETAL FIXATION DEVICE

Removal of the ESFD is accomplished with the horse standing, with use of light sedation and a special pin removal device supplied by the manufacturer. The foot plate is removed using a sharp box knife, cutting the material at the junction of the hoof and plate.

An electric Sawzall or hacksaw can be used to cut the lateral sidebar tube just below the lower tapered sleeve on one side of the frame very quickly.

The nuts are removed from the threaded pins on the tapered sleeves. The pin extractor is placed over the distal tapered sleeve and the pin engaged and removed by turning the extractor with an end wrench. This is repeated as necessary on the proximal tapered sleeve. Once the pins have been removed, the frame can be lifted away. A standing cast is usually applied to preserve the structure and function of the extremity for an additional time until healing is sufficient for unrestricted weight bearing. It is at this juncture that the TSPs can be incorporated into the cast if desired. Radiographic examination is helpful in making these decisions.

RESULTS OF TREATMENT (2008)

Of 27 horses managed with the original ESFD (three 9.6-mm unprotected pins through the McIII or the MtIII) over a period of 14 years, nine survived (33%). The complication of the McIII or the MtIII fracture through pin sites in six horses led us to abandon this device and introduce the two-pin TSP ESFD in 1996. Early experience with the TSP ESFD has been favorable, and five (71%) of seven horses survived; only one horse developed a fracture through the pin site. Both nonsurvivors had chronic infections of the original fracture site and laminitis on the contralateral forelimb. Four fractures were open, six were comminuted fractures of the proximal phalanx (see [Figure 87-1](#)), and one was a comminuted fracture of the middle phalanx.

Chapter 88

Counterirritation

David R. Ellis and Stephen P. Dey III

BRIEF HISTORY AND OUTLINE OF TECHNIQUES

Counterirritation techniques have long been a part of veterinary therapy, particularly in horses. Major veterinary texts, such as those by Percivall,¹ Wooldridge,² and even Stashak³ as late as 1987, devoted considerable attention to indications and techniques. To some this now seems misguided and even cruel, but one has to read only a few of the older texts to admire the authors' inquiring minds and their thorough observations on matters medical and particularly orthopedic. They were not far from the truth, but they did not have the benefit of modern anesthetics or imaging equipment to learn and apply more direct and rational therapies. Techniques currently used include hot or cold firing and blisters, but use of those therapies is much reduced because of changes in horse ownership and veterinary attitudes. This chapter considers both British (DRE) and North American (SPD) perspectives.

BLISTERING

Limited availability of ingredients and ignorance of preparation and safe use has restricted blistering of horses in the United Kingdom. Although veterinary surgeons or equine wholesalers are the source, the horse owner is usually the user. More severe blisters, such as those containing cantharides or croton oil, are used less commonly than the working blisters that are iodine or mercuric iodide based and mainly used on splints, sore shins, or curbs. The technique involves rubbing or brushing the liquid preparation onto the clipped skin once daily until a scale forms. The horse is kept in light exercise, such as walking, trotting, or hack cantering, and this phase usually is undertaken after the initial rest and antiinflammatory treatment have removed heat, swelling, and pain (i.e., 7 to 10 days after initial clinical signs). When the heat and soreness from counterirritation has settled, which takes 2 to 3 weeks, the horse resumes work.

Irritation from working blisters is minimal, and protective measures such as antiinflammatory treatment, keeping the horse crosstied, or fitting a bib or cradle are not necessary.

Strong blister was made mostly from cantharides (Spanish fly) or croton oil, but nowadays these ingredients are difficult to obtain and, because they are not licensed drugs in the United Kingdom, are probably illegal for a veterinary surgeon to import without a permit. As a consequence the strong blister that is used most commonly is made as a cream using red mercuric iodide. The skin is clipped and the blister rubbed into the area for 5 minutes. Excess is removed and petroleum jelly is applied to flexor surfaces distal to the blistered areas. The horse is kept shod

for blistering, in case it paws the ground, and a neck cradle is applied until the initial inflammatory phase has subsided. It is essential that the horse continues walking exercise, usually 30 minutes twice daily. A substantial risk of laminitis or lymphangitis exists if blistered horses do not have this regular exercise. When blisters form and burst, they are left alone and sprayed with antibiotic powder. Rarely is the reaction severe enough to warrant antiinflammatory treatment. After 10 days the blistered areas of the legs are smeared with petroleum jelly, which is left on overnight and then washed off with warm water and soft soap. This softens and lifts the scabs free, without causing bleeding or further irritation. Any blistered areas that are still moist are dressed with antibiotic wound powder, and walking is continued. Scabs that persist after 7 to 10 days are removed by repeating this procedure. After 6 weeks the horse can be turned out to pasture or start light ridden exercise. The program for a return to training depends on the nature and progress of the original injury.

Areas treated most commonly with strong blister are the digital flexor tendon region of forelimbs and the fetlock joints. Indications are tendonitis, tenosynovitis, suspensory desmitis, and chronic effusion of fetlock joints.

In North America, curbs frequently are treated by blistering (see Chapter 78), and both hindlimbs are usually treated. The area is clipped and rubbed aggressively for 3 minutes with medical-grade turpentine and then with kosher salt for 3 minutes, alternating for a total of 15 minutes. This is repeated once daily for 3 days. The horse is exercised immediately after each treatment for at least 20 minutes. The skin excoriates and remains thickened and inflamed for some time, but therapeutic effects are almost immediate.

Blistering also is used to manage suspensory desmitis, tendonitis, sesamoiditis, and other fetlock problems. The severity of the injury determines which blister is used and the degree of exercise modification. If horses with suspensory desmitis or tendonitis are being treated, the metacarpal or metatarsal region usually is wrapped (bandaged) with a gauze layer, a leg quilt, and a bandage to control swelling. Moving areas such as the carpus or tarsus are not wrapped.

The blistering process is allowed to continue for 5 days, and then a firing paint is applied to the area for another 7 days, with the bandages reset every day if the blistering process involves the metacarpal (metatarsal) or fetlock region. After the firing paint application period ends, usually an iodine glycerin-based product is applied every day to soften the blister scabs and help lift the outer skin layers that have separated. Once a horse begins to be painted with the firing paint, it can be exercised on a walker or in a small paddock. This reduces inflammation and begins to reestablish normal venous and lymphatic flow.

Internal blisters have more widespread use in North America compared with Europe. A 2% iodine mixture, in almond oil or a lighter base, can be injected into tissues. One author (SPD) treats muscle soreness by injection of 1 mL of internal blister per site using an 18-gauge needle of variable length, depending on the depth of the injection. The mechanism of action is unknown, but trainers usually report that the gait improves (see Chapter 47).

Internal blisters also are used to treat horses with suspensory desmitis, curbs, and splints. Varied results may reflect the inconsistency of the available products.

CAUTERY OR FIRING

Cautery or firing is performed less frequently in the United Kingdom since the Royal College of Veterinary Surgeons deplored the practice in 1991. Cautery or firing is used for horses with injuries to soft and hard tissues, and some clinicians and clients are still enthusiastic about its value. Pin or needle firing is the most common technique.

Cold firing is used mainly for horses with persistent sore shins or splints, and the thermal injury is made with liquid nitrogen (see Chapter 89). The procedure is done soon after the initial inflammatory phase has subsided and is preferred for horses with intractable injuries that have not responded to antiinflammatory measures or blisters. The area is clipped, the horse is sedated, and local anesthesia is administered. An ordinary firing iron can be cooled by leaving it in the liquid nitrogen, or a special "gun" point freezes a small area of skin. Spots of lubricant gel on the areas to be fired improve the contact. The pattern should not allow the frozen spots to be closer than 3 cm apart. No systemic or local treatment is needed, and the horse is kept in walking exercise for 6 weeks. Ultimately the skin develops persistent white point scars. Results have been good enough to ensure its continuing use, but the rationale is difficult to ascertain. Cold firing probably causes local analgesia of some duration within periosteal nerves and may necrose small areas of the periosteum and underlying cortical bone.

Acid firing enjoyed a vogue several years ago but has deservedly fallen from use. Concentrated nitric acid was soaked into a small cork, which was then pressed onto the clipped and desensitized skin. The inflammatory reaction was substantial, but, like line firing, acid firing appeared to affect only the skin and not the underlying tendon.

Line or bar firing was used for horses with tendonitis or curbs. For the lines to be made evenly, the area was clipped the day before firing and covered with a mustard plaster overnight, which caused subcutaneous edema to smooth out the grooves between the structures before firing. Curved, blade-shaped irons were used, and management was the same as for pin firing. One author (SPD) has minimal experience with this technique but agrees with Silver and colleagues⁴ that it would not be "a useful therapeutic exercise."

Horses are still pin fired regularly in the United Kingdom. The procedure is used for horses with superficial digital flexor tendonitis, suspensory desmitis, and sesamoiditis and has value for those with persistently painful splints. Pin firing is no longer used for distal hock joint pain or carpalitis. The horse is fired after the initial inflammatory response has subsided and when the area is no longer warm or painful, 4 to 6 weeks after the injury. The area is clipped and anesthetized before being dressed with surgical spirit. Firing is started 10 to 15 minutes later and patterned no closer than 3 cm apart over the structure being treated. It is important to use a fine point so that minimal burning of the adjacent skin occurs. The point penetrates the underlying tendon or periosteum. An iodine-based ointment is then applied, and petroleum jelly is smeared distally, particularly in the flexural regions of

joints. The horse is crosstied, or fitted with a cradle, and walked in hand twice daily for 30 minutes. As for blistered horses, walking is essential. It is wise to keep front shoes on, and only rarely is analgesia indicated. The area is powdered with antibiotic daily and after 10 days is smeared with petroleum jelly, which is left on overnight and washed off the following morning, as previously described. Walking exercise continues for at least 6 weeks, and then the horse can start to spend increasing periods of time turned out in a paddock. The horse should not return to training for about 1 year after a soft tissue injury. Those horses that have had bony tissue fired, such as with splints, can return gradually to training after 6 weeks of walking.

In North America, pin firing is used mostly to treat horses with splints, curbs, tendon and ligament injuries, and fetlock and surrounding soft tissue injuries. A similar pattern is used for pin firing curbs and splints (SPD). Marks are made down the center of the lesion, 1 cm apart. Alternating rows, medially and laterally, 0.5 cm between the original marks, are then made. When firing tendons or ligaments, a similar pattern is used, but the point never goes through the deep layer of epidermis. However, areas of maximum damage are refired to ensure deeper penetration to focus the healing process. The horse may require sedation and analgesia for 24 hours after treatment to control pain. The area is painted with firing paint for 10 days; it is covered with gauze, a quilt, and bandage. Another 30 days of rest are required before reevaluation of the horse. The total convalescent period depends on the initial injury. In sports horses, use of cryotherapy to treat splints and some soft tissue injuries is more common. Although cryotherapy is less invasive, the procedure is often less effective (see Chapter 89).

Current thoughts on thermal injury to tissues still emphasize the gulf between veterinary science and veterinary practice. Although much excellent science has illuminated the injury and healing of strained tendons, such injuries are still the most substantial injuries a flat racehorse can sustain and are a long-term threat to the horse's continuing career. Horses that race over fences (steeplechasers) or hurdles seem to manage better than those that race at a faster pace on the flat. The expectation that counterirritation would produce a fiber pattern with crimp and better-quality collagen may have been ill-founded, but the successful results that veterinarians have experienced over the years need to be explained. Perhaps the mechanical side effect of pin fire scars, evening out the differing strength and elasticity along the length of the injured tendon and in the contralateral limb, has kept pin firing in equine orthopedics. Beyond enforced rest and low-grade exercise, seeing benefit accruing from blisters used in horses with tendon strain is difficult.

Aggressive antiinflammatory treatment in the early postinjury phase is important, but one author (DRE) is uncertain if subcutaneous corticosteroids are essential for a good long-term result.

Treatment regimens such as intralesional glycosaminoglycans or β -aminopropionitrile fumarate have disappointed, and the results of surgical splitting or desmotomy of the accessory ligament of the superficial digital flexor tendon have not always justified the expense in the United Kingdom. Prolonged rest and controlled exercise regimens seem as successful as any treatments.

The choice of treatment still emerges from consensus among the experiences of the veterinary surgeon, the trainer, and the owner. All equine veterinary surgeons share the fervent hope that successful and rational therapy for horses with strained flexor tendons will emerge soon.

Restrictions on using firing by the Royal College of Veterinary Surgeons were initiated by a question in the Houses of Parliament about the firing of horses. The Horserace Betting Levy Board then funded a research program by the Bristol group, led by Professor Ian Silver. This work was published in a supplement to the *Equine Veterinary Journal*.⁴ Extensive discussion followed, but in 1991 the Royal College of Veterinary Surgeons tried to outlaw the technique of firing tendons by declaring that they deplored it and would bring disciplinary action against any member performing it. This was not well received by a substantial number of respected equine veterinary surgeons, and the policy was one that had been poorly thought through, did not recognize hard tissue firing, and proved to be unenforceable. A compromise was later reached, whereby veterinary surgeons had to show that other treatments had

failed and to justify their choice of firing a particular horse. The technique continues to be used, but since the introduction of ultrasonography and the retirement of veterinarians who preferred it, the use of firing has diminished considerably. One author (DRE) believes that firing would have gradually disappeared without legislation.

Techniques currently used in equine orthopedics have become more conservative since the introduction of ultrasonography and the development of finer sensitivity among horse owners. The regular monitoring of these horses has enabled more rational advice to be given regarding healing of the lesions and programming of exercise. Thus the implementation of direct therapy has taken second place among certain groups of clinicians. They remain cynical about therapy while maintaining client confidence through regular observation of the horse. Splitting or needle decompression of a tendon core lesion soon after injury is a rational first step, followed by regular monitoring and controlled, graded exercise throughout a long convalescence. The old adage of "the longer the rest, the better" still seems valid.

Chapter 89

Cryotherapy

Kjerstin M. Jacobs and Thomas P.S. Oliver

Cryotherapy has been used widely in veterinary medicine since the 1970s, primarily for tumor ablation. Percutaneous cryotherapy, called *freeze firing* or *freezing*, is a useful palliative technique for various musculoskeletal disorders in the horse, but little research has been published on specific techniques or results.¹⁻⁴ Most of the information in this chapter comes from our clinical experience using cryotherapy to manage selected lameness conditions. Cryotherapy generally is used for pain management, and our recommendations are made assuming the horse will continue or resume athletic performance. The term *cryotherapy* (cold therapy) is sometimes used to refer to intentional cooling of a body part to reduce inflammation or the effects of inflammatory mediators. For instance, cryotherapy is used to prevent laminitis by inducing digital vasoconstriction (see Chapter 34).

MECHANISMS OF CRYONECROSIS

Freezing mammalian tissue results in direct and indirect cell destruction. Direct cell injury occurs by formation of intracellular and extracellular ice crystals, which destroy cell walls and cause intracellular dehydration, respectively. Intracellular dehydration causes severe electrolyte concentration and pH shifts, which damage lipoprotein membranes and organelles. Loss of cellular homeostasis results in cell death. Indirect cell injury occurs by damage to the endothelium of arterioles and venules, causing increased

vascular permeability, edema, and hemoconcentration. Local tissue damage occurs from thrombosis and infarction of small vessels. Two rapid-freeze, slow-thaw cycles are used. Rapid freezing maximizes intracellular crystal formation and crystal size. Slow thawing causes additional cell damage by a process of recrystallization, during which time crystals increase in size before melting. Precooled tissue freezes faster than normal tissue; therefore a second freeze-thaw cycle optimizes the processes of tissue destruction.

Because cryotherapy causes tissue destruction in situ, fibrous structures such as epineurium remain intact. This allows for regeneration of large myelinated nerves. Experimental percutaneous cryotherapy of equine palmar and plantar digital nerves resulted in neuropraxia (temporary ablation of nerve function, with the axons remaining intact) or axonotmesis (wallerian degeneration of axonal tissue, with the fibrous supportive tissue remaining intact). All nerves regenerated.⁵ The degree of nerve damage is temperature dependent, with lower temperatures resulting in longer duration of analgesia.⁶

Presumably, percutaneous cryotherapy causes destruction of local type C nerve fibers. Type C fibers are small, unmyelinated, nociceptive nerve fibers that contribute to chronic pain. The inflammatory response to cryotherapy appears to cause thickening and fibrosis of certain soft tissues, such as the suspensory ligament and subcutaneous tissues, and although this effect has not been studied, the clinical result is a stronger ligament and one less likely to be reinjured in the same location. Cryogens must be used judiciously on the distal aspect of the limb to avoid cryonecrosis of tendon, ligament, joint tissues, or cortical bone.

BASIC TECHNIQUE

Cryotherapy instruments and cryogens are described elsewhere, and only basic principles are discussed here.⁷⁻⁹ Instruments used to apply cryogens vary from simple

cryoprobes to cryounits with continuous closed-system flow of cryogen liquid. We use liquid nitrogen that is stored in a commercial 10- to 20-L tank. For all techniques we use individual brass probes, 1.5 cm in diameter (Figure 89-1), precooled in liquid nitrogen and positioned on the lesions for a double freeze-thaw cycle consisting of freezing (60 seconds), thawing (60 seconds), and freezing (60 seconds). Local edema formation is minimal and has no effect on the second freezing cycle. Earlier work suggested that a thaw duration of 15 seconds was optimal, but our modified cycle appears effective.⁴ We prefer to use solid metal probes, because consistent freezing to a specific depth is easy to control (Figure 89-2). The cooling ability of solid metal probes has been questioned, but in one study solid metal probes were most effective in freezing to specific depths.⁷

Cryotherapy is well tolerated by most horses, but sedation and a twitch are used. Local analgesia (a ring block proximal to the freeze site) may be necessary for highly

Fig. 89-1 • Solid brass cryoprobes commonly used for cryotherapy in the horse.

Fig. 89-2 • Cryotherapy is being used to manage pain associated with an exostosis of the fourth metatarsal bone in a Standardbred racehorse. A double freeze-thaw cycle has been used in one site, and the probe is being applied at a distal site.

strung or fractious horses. The area over the lesion is clipped with a No. 40 blade and cleaned of gross contamination with iodophor or chlorhexidine solution. The limb is dried, and a 0.5-cm-thick layer of water-soluble gel is applied generously over the site. This layer provides a template to ensure accurate positioning for the second freeze cycle.

The metal probe tip is applied to the skin for 60 seconds, then removed to allow thawing, and reapplied (see Figure 89-2). No benefit accrues from a third freeze-thaw cycle, and in fact a third cycle may lead to underlying bone necrosis. Freeze sites should be located 1 cm apart in staggered, parallel rows that cover the lesion site and extend 1.5 cm beyond the margins of the lesion. If freezing sites are closer than 1 cm, the areas of skin necrosis will coalesce and later slough.

After completion of the procedure, the leg is cleaned of lubricant and the sites are covered with an antibacterial spray. The leg should be left unbandaged, but it is kept dry, and antibacterial spray is applied daily until skin healing is complete. Local soft tissue swelling and edema develop and persist for 7 to 10 days and then gradually resolve. The administration of antiinflammatory agents should be avoided, because this medication limits the intended effect of cryotherapy. Percutaneous cryotherapy destroys melanocytes in skin cells, so hair regrowth will be white. This negative cosmetic effect should be considered when discussing complications of cryotherapy.

TREATMENT OF SPECIFIC LESIONS

Diagnosis always should be confirmed using diagnostic analgesia, because results obviously are improved if the painful area is identified correctly. Most horses return to full function and race performance within several days to weeks, but some (e.g., those treated for severe suspensory desmitis) require up to 120 days of rest after treatment. When managing horses with suspensory desmitis, rest is paramount but is a source of frustration for trainers and owners, who often want to rush a horse back to the races.

Splint Exostoses (Splints)

Horses with exostoses of the second, third, and fourth metacarpal and metatarsal bones should not be treated until acute inflammation has subsided, because cryotherapy may exacerbate periosteal reaction. Horses are given 2 weeks of rest during which a poultice is applied for 5 days, followed by the application of a cedar oil blister for 5 to 7 days. Scurf from the blister is removed by sweating before cryotherapy is performed. Horses with chronic splints can be managed with cryotherapy without this 2-week preparation period. After cryotherapy in any horse, stall rest is recommended for 3 to 5 days. The horse then may be jogged or galloped lightly and brought back into full training within 7 to 10 days after treatment. Prognosis is good for return to racing. The procedure may be repeated at the same site, or at additional sites, if pain recurs or new sites develop.

Second and Fourth Metacarpal or Metatarsal Bone Fractures

Ostectomy of distal fragments of the second or fourth metacarpal or metatarsal bones is ideal, but in some horses

surgery is not an option and cryotherapy can provide analgesia. Acute inflammation must be resolved before treatment. A single freeze site is placed directly over the fracture site, and four more sites are frozen in a circular pattern around the fracture site. Prognosis and rest depend mostly on extent of associated suspensory desmitis, if present, because horses with simple splint bone fractures can return to work immediately. Horses with mild suspensory desmitis have a good prognosis for return to racing and usually receive 60 days of rest after cryotherapy. Horses with severe suspensory desmitis require a minimum of 120 days of rest and have a guarded prognosis.

Periostitis of the Third Metacarpal Bone (Bucked Shins)

Cryotherapy can be used to manage pain associated with bucked shins (see Chapter 102) once acute inflammation has subsided. A dorsal cortical fracture of the third metacarpal bone must be ruled out, because cryotherapy in horses with fracture is contraindicated. Once swelling and palpable pain resolve, cryotherapy is performed using three vertical rows of eight or nine freeze sites per row. After cryotherapy, 2 weeks of stall rest with handwalking followed by 4 weeks of turnout exercise is given. Prognosis is excellent, and few horses require additional treatments.

Suspensory Desmitis

Ultrasonography must be performed first to determine the severity and extent of desmitis (see Chapters 16 and 72). Before cryotherapy, acute inflammation is managed using rest, antiinflammatory medication, and local therapy, such as cold-water hosing and poultice application. Cryotherapy is then performed using a vertically oriented row of freeze sites, beginning 3 cm proximal and extending 3 cm distal to the lesion. It is crucial that freeze sites be 1 cm apart and that each site be located directly over the body of the suspensory ligament and not over the deep and superficial digital flexor tendons. Cryotherapy is performed over each affected branch. If suspensory body desmitis is present, the procedure is performed on the medial and lateral aspects. Horses are given a minimum of 2 weeks of stall rest with handwalking, followed by 2 weeks of turnout or swimming physiotherapy. The suspensory ligament and overlying tissue become fibrotic and rigid after treatment, and, although tissue may appear strong to laypersons and the horse may be sound at the walk and trot, it is essential to recommend a conservative return to training and racing. Prognosis always is guarded, but most Standardbred racehorses return to racing. Suspensory desmitis is often a compensatory condition caused by contralateral limb lameness, or lameness in a diagonal or ipsilateral limb, and management of the primary problem is critical in decreasing recurrence of suspensory desmitis. Cryotherapy is seldom effective for long-term management of suspensory desmitis if primary lameness continues. After developing suspensory desmitis, horses may drop in race class and value, but cryotherapy has been a useful adjunct in managing pain and allowing continued racing. The Editors believe that cryotherapy should not be performed for suspensory branch and body lesions in Thoroughbred racehorses

because of the risk of catastrophic failure of the suspensory ligament (see Chapter 104).

Distal Hock Joint Pain (Bone or Jack Spavin, Cunean Tendonitis)

Cryotherapy is useful in managing horses with distal hock joint pain. A double horizontal row of freeze sites over the proximal and distal borders of the cunean tendon is used. The horse is given stall rest with handwalking for 2 weeks. Prognosis is excellent for return to racing in the Standardbred racehorse.

Osteoarthritis of the Proximal Interphalangeal Joint

Chronic pain from osteoarthritis of the proximal interphalangeal joint (see Chapter 35) may be alleviated partially by cryotherapy. Cryotherapy is most useful in horses in which palmar digital neurectomy fails to abolish all pain originating from the proximal interphalangeal joint, especially in those with severe bone lysis and proliferation and in which arthrodesis is not an option. Pain relief sometimes can be achieved by placing cryotherapy sites 1 cm apart, encircling the proximal interphalangeal joint proximal to the lesion, and directly over the sites of bony proliferation. It is important to avoid the superficial digital flexor and deep digital flexor tendons. After treatment, horses are given stall rest with handwalking for a minimum of 3 weeks. Prognosis is guarded.

Curb

Curb, a collection of injuries located along the distal, plantar aspect of the tarsus, can be managed successfully using cryotherapy (see Chapter 78). Acute inflammation must be resolved, a process that may take as long as 7 to 10 days. The number of cryotherapy sites depends on the size of the curb, but 8 to 12 sites are usually required. Horses are given stall rest with handwalking for 2 to 3 weeks, but further rest depends on the structure involved and severity of initial lameness. The technique works best on horses with curb as a result of inflammation of the peritendonous tissue or mild superficial digital flexor tendonitis (see Chapter 78). Prognosis is usually good, but some horses require additional treatment within 6 to 12 months.

Cryoneurectomy

Cryotherapy can be useful to provide analgesia to the palmar or plantar aspect of the digits, but the degree of cryoanalgesia depends on the technique used. Percutaneous cryoneurectomy has limited clinical use, because only temporary pain relief (3 to 4 weeks) is achieved.⁵ Cryoneurectomy has been found to be more effective in producing neuroanalgesia than simple transection, but the former procedure requires a surgical approach.¹⁰ The nerves are exposed and transected, and the proximal ends are frozen.

A modified approach can be used.⁵ The palmar or plantar digital nerves are exposed, and a double freeze-thaw technique is used to freeze the nerve within the perineurium, but the nerve is not transected. Analgesia is longer than with percutaneous cryotherapy, but having to expose the nerves limits the practical application of this technique.

Tendonitis

We feel that management of superficial digital flexor or deep digital flexor tendonitis with cryotherapy is contraindicated. After cryotherapy, fibrous tissue formation along the tendon fibers and possible scarring and adhesions of

the digital flexor tendon sheath can occur and limit prognosis. Although we are aware of horses that have raced after cryotherapy for tendonitis, we suggest that other management options be explored (see Chapters 69 and 70).

Chapter 90

Radiation Therapy

Alain P. Théon

Radiation therapy is the use of ionizing radiation to treat people and animals with malignant tumors and, occasionally, selected benign diseases. These diseases can be classified as inflammatory, degenerative, and hyperproliferative. The analgesic action of ionizing radiation for chronic orthopedic conditions has long been recognized and was first reported soon after the discovery of x-rays.¹ The effectiveness of radiotherapy has been demonstrated in people with painful, degenerative joint diseases that were refractory to first-line conservative treatment—for example, nonsteroidal antiinflammatory drugs (NSAIDs) and physiotherapy.² In horses radiation therapy was found to be effective for painful degenerative and inflammatory musculoskeletal conditions early in the development of veterinary radiation therapy.³ However, limited access to treatment facilities for horses, fear of the long-term hazards of ionizing radiation, and the availability of potent antiinflammatory drugs have decreased the impact of radiation therapy in the overall management of equine lameness. Although most clinical studies on using radiation therapy for equine chronic orthopedic conditions were reported in the 1960s and the 1970s, interest is currently renewed because of a better understanding of the mechanisms of action of radiation and identification of specific indications for treatment. The emergence of the specialty of veterinary radiation oncology will provide the expertise and personnel for expanding the applications of radiation therapy for treatment of noncancerous conditions at veterinary schools and private referral practices. Controlled studies are required to validate the experience-based indications, compare radiation therapy with other treatment options, and improve radiation parameters (single and total dose and fractionation). Several clinical trials have been undertaken at our institution, but adequate long-term observations and reliable assessment of clinical data according to objective orthopedic criteria are difficult to document.

RADIOBIOLOGICAL ASPECTS

Radiotherapy of nonmalignant conditions requires low doses of radiation, usually one fifth to one tenth the dose used in cancer treatment. The radiobiological mechanisms involved in the therapeutic effects of low-dose radiation used for benign conditions are different from those

mediated by high radiation doses used to treat cancer. The therapeutic effects of radiotherapy for cancer result from cell death and inhibition of tumor cell proliferation. The therapeutic effects of low-dose irradiation in treating painful musculoskeletal disorders result from several distinct mechanisms that are not fully understood. Radiotherapy does not work via one single or particular mechanism but rather through a complex interaction of different effects on many cell types.

Early data indicating an increase in dermal blood flow and cutaneous temperature after treatment⁴ led to the misconception that radiation therapy produces a deep counterirritation that promotes increased blood flow and cell recruitment to the treated area to expedite healing.⁵ This theory, however, is not supported by any current data. The previously observed effects merely reflect inaccurate dosimetry that resulted in high radiation doses to the skin. In addition, evidence shows that counterirritation during the chronic stage of inflammation prolongs healing time and results in further damage.⁶

Modern theories on mechanisms of low- to medium-dose radiation for treatment of noncancerous conditions are based on new experimental data. The mechanisms are grouped into antiinflammatory effects, analgesic effects, and antiproliferative effects.

Antiinflammatory Effects

Whereas good evidence exists that high radiation doses induce strong inflammation in normal tissues, equally good evidence exists that low radiation doses have the opposite effect in inflamed tissues. Low-dose radiation therapy has a pronounced antiinflammatory effect on acute and chronic inflammatory processes in joints and periarticular tissues. In experimental animal models of osteoarthritis (OA), low-dose irradiation reduced bone loss, synovial proliferation, cartilage degradation, joint swelling and pain.⁷

The antiinflammatory effects of irradiation are not caused by cytotoxic effects, because the low doses used are not lethal to cells, and activated inflammatory cells, including lymphocytes,⁸ monocytes, and macrophages,⁹ have lost the clonogenic potential and are therefore radioresistant.

Clinically observed antiinflammatory effects of low-dose radiation do not result from elimination of inflammatory cells but appear to be caused by functional alteration and regulation of cells involved in the inflammatory response including endothelium, macrophages, and granulocytes.¹⁰ Adhesion of white blood cells to activated endothelial cells and induction of nitric oxide synthetase in activated macrophages are reduced. Radiation decreases leukocyte adhesion, thereby reducing recruitment of granulocytes to inflamed tissue, which results in decreased proteolytic enzyme release and reduced tissue necrosis.

Radiation-induced inhibition of nitric oxide production results in reduced inflammatory reaction.^{9,11} Good evidence also exists that radiation-induced reduction of monocyte and macrophage cytokines prevents excessive fibrosis.¹² This may explain subjective reduction in joint capsule fibrosis and the functional improvement after treatment of OA.¹³

Analgesic Effects

The analgesic effects of ionizing radiation on degenerative and inflammatory disorders are manifested by early effects of short duration, followed by long-term, delayed effects. The delayed effects, characterized by long-lasting pain relief that develops several weeks after treatment, result from the antiinflammatory effects of radiation. Early effects, characterized by fast pain mitigation, result from radiation-induced modulation of the afferent nociceptive pathways. Analgesia involves non-opioid- and opioid-mediated mechanisms. Although the opioid-mediated analgesia is poorly understood,¹⁴ the nonopioid mechanisms (which include modification of pain transmission and perception) appear to be mediated in part by nitric oxide.¹⁵⁻¹⁷ Radiation-induced decrease in local nitric oxide production results in desensitization of the nociceptors¹⁸ and prevention of neuropathic pain development.¹⁹

Antiproliferative Effects

Ionizing radiation inhibits cell proliferation and temporarily reduces the production of new cells. This mechanism is assumed for prevention of new bone growth and treatment of chronic synovitis. Low-dose radiation does not interfere with normal bone healing, because native osteoblasts are not irreversibly inactivated by radiation. However, irradiation can inhibit excessive new bone formation from existing bone and within muscle after trauma or surgery. Radiation target cells are pluripotent mesenchymal stem cells that are stimulated to proliferate and differentiate into osteoblasts after trauma (e.g., injury or surgery) as a result of the healing process.²⁰

Surgical trauma initiates a sequence of events during which cell proliferation takes place within a specific time. Radiation administered during this period induces a delay in cell production that results in a full and permanent therapeutic effect. In people the ability of irradiation treatment to interfere with the formation of heterotopic bone is limited to 4 hours before surgery to 48 hours after surgery.²¹ In horses the timing of radiotherapy to prevent new bone growth is also important, and irradiation usually is performed immediately after surgery. In ponies with experimental osteochondral defects in the antebrachio-carpal and middle carpal joints, radiation therapy was not effective in preventing periostitis and periarticular osteophytes when given 6 weeks after surgical trauma.²¹ For mature ossification, irradiation alone has no value beyond pain control.

In treating chronic synovitis the antiproliferative effects of irradiation only delay progression of the disease process, because no critical period exists during which cell proliferation is required for the expression of damage. The goal of radiation-induced synovectomy is to ablate inflamed, proliferative synovium, with the expectation that after treatment the regenerated synovium will be free of disease.

Treatment Side Effects

Much of the concern surrounding using irradiation to manage benign conditions is the presumed risk of radiation-induced malignancy. The low doses used, however, are below the threshold associated with an identifiable risk of malignant transformation. In horses, development of in-field sarcoma secondary to radiation therapy to manage benign conditions has not been reported. Reported skin and bone damage likely reflect inadequate treatment techniques according to modern standards.

Skin Damage

Skin damage including epilation, dry desquamation, and regrowth of depigmented hair was often seen when low-energy orthovoltage radiation or insufficiently filtered radioisotope sources were used. The use of modern irradiation techniques and high-energy megavoltage radiation has eliminated the risk of skin overdose, and skin reactions are no longer observed.

Osteopenia

Similar to findings in people, experimental^{22,23} and clinical²⁴ studies in mature horses have shown that low doses of radiation (<10 gray [Gy]) do not affect bone density measured radiologically and do not increase risk of fracture. Although irradiation inhibits excessive bone remodeling and periosteal reactions after surgery, it does not appear to interfere with bone healing. In immature horses, the use of radiation therapy to treat periostitis and OA is discouraged because radiation interferes with bone growth.²⁵

IRRADIATION TECHNIQUES

The administration of ionizing radiation is analogous to the prescription of medications based on pharmacological principles. Irradiation of nonmalignant diseases should be carried out by a veterinary radiation therapist familiar with all technical and clinical aspects of modern radiation therapy. Long-term follow-up has to be assured because of the responsibility for radiogenic late effects.

Radiation doses are expressed in Gy, the *Système International* unit, which has replaced the roentgen (R) and the rad (radiation absorbed dose; 1 Gy = 100 rad).

Before treatment, areas to be irradiated must be identified radiologically to ensure delivery of the radiation dose to the appropriate target volume. Radiotherapy techniques vary considerably based on tissue involved, location, and equipment available. Two methods of irradiation available for treatment of benign lesions in horses are teletherapy (external beam therapy) and brachytherapy.

External Beam Irradiation

Teletherapy involves the external administration of radiation therapy (at a distance of 50 to 100 cm from the area to be treated) by machines that emit x-rays or γ -rays, which can be collimated and directed precisely at the lesion. No difference exists in the mechanism of action between x-rays and γ -rays. In the past, treatments were done with low-energy orthovoltage x-ray units²⁶⁻²⁸ producing low-energy x-rays (60 to 90 keV), and the radiation dose was given in a series of three to five exposures. Dosimetry was inaccurate because of the poor penetration of radiation and movement of the standing horse, which was physically

restrained during treatment. Currently, teletherapy is done exclusively with megavoltage (4 to 6 megavolts [MV]) radiation delivered by linear accelerators that produce high-energy x-rays or telecobalt units that produce high-energy γ -rays.²⁹ The advantages of megavoltage radiation include skin sparing, deep penetration into tissue, and precise dosimetry. A distinct disadvantage of this technique is the need for general anesthesia to ensure accurate positioning and immobilization of the horse during treatment. Delivering a single radiation dose ranging from 8 to 12 Gy takes 6 to 8 minutes, so complete immobilization is crucial. Accurate radiological definition of the area to be treated is essential for efficacy and sparing of the surrounding normal tissues.

This treatment method requires high investment in equipment and involves the registration of the radiation therapy unit with government agencies. As a result, such treatments for horses are usually provided at veterinary schools.

Brachytherapy

Brachytherapy is a treatment in which radioactive sources are applied directly to the area to be treated. The short distance between the radiation source and the lesion allows delivery of the radiation dose with minimal exposure to surrounding, uninvolved normal tissues. The disadvantage is radiation exposure to the radiotherapist during positioning and removal of the sources and to personnel responsible for the care of horses during treatment.

Treatment involves using sealed radioactive sources implanted directly into tissues (interstitial brachytherapy) or arranged into an applicator positioned on the skin above the area to be treated (surface brachytherapy). An alternative approach consists of injecting unsealed radioisotopes into a joint space (intracavitary brachytherapy) to deliver the radiation dose directly to the synovium.

This treatment method requires minimum facility and equipment investment, but obtaining a license for laboratory and industrial use of radioactive materials is necessary. This type of license is issued only to an individual who can document extensive training and experience in the safe use of radioisotopes for medical and veterinary purposes.

Interstitial Brachytherapy

Radon gas (²²²Rn) in beads and radioactive gold (¹⁹⁸Au) pellets that emit γ -rays have been used for interstitial brachytherapy. Radioactive sources are inserted permanently and slowly deliver the radiation dose to the surrounding tissue, until complete decay occurs. To minimize personnel exposure, the implantation procedure is done in two steps: first, the insertion of unloaded needles in tissues according to specific radiation planning rules; and second, the loading of the needles with radioactive sources using a special implantation instrument. Achieving consistently satisfactory implants requires a good deal of practice. Treatment is expensive, because radioactive sources can be used only once. This technique is now used rarely and is not allowed in most areas of the United States (the reader may inquire at the local department of social and health services for state regulations, or with the appropriate government agency in other countries). The major drawback is the potential radiation hazard, because the implant is still radioactive when the horse is discharged from the hospital.

Surface Brachytherapy

Surface brachytherapy (plesiotherapy) involves using a surface applicator containing an array of linear radioactive sources. The most common brachytherapy technique involves inserting radioactive sources in the form of rigid needles applied on the skin overlying the lesion. Radioactive cobalt (⁶⁰Co) and cesium (¹³⁷Cs) emit a useful beam of γ -rays and are the most common radioisotopes used. Rigid (cast)³⁰ or flexible (pack)³¹ applicators must be light, immobile, well fitted, and comfortable because they are left in position for an extended period to deliver the radiation dose. Dose distribution in tissues depends on arrangement and number of radioactive sources. Treatment doses range from 5 to 15 Gy, given at a low dosage rate over 48 to 72 hours (Table 90-1). Horses must be confined to an isolation facility during treatment to manage the radiation safety hazard posed by large ambient exposure rates around the applicator. Once the dose has been delivered and the pack has been removed and stored in a shielded container, a radiation hazard no longer exists. The horse then can be discharged safely from the hospital.

Surface application has a distinct disadvantage over a therapeutic x-ray machine, because movement of the pack above the skin affects the radiation dose distribution on the area to be irradiated. The potential for source damage, release of radioactive material, and contamination of the facility for several years are other disadvantages.

Intracavitary Brachytherapy

Intracavitary brachytherapy is a new approach developed to concentrate the radiation dose in the target tissue and is used primarily to treat synovitis. Radiation is delivered by intraarticular administration of unsealed β -emitting radioisotopes. The short emission range of the β particles (electrons) provides a high radiation dose to the synovium in contact with the radioisotope without causing damage to articular cartilage or surrounding skin. Diseased synovium is ablated, but the effects on the periarticular tissues and underlying cartilage are minimal.

Several formulations have been developed to prevent leakage of radioisotope from the site of injection. Radiocolloids labeled with radioactive gold (¹⁹⁸Au), yttrium (⁹⁰Y), phosphorus (³²P), and rhenium (¹⁸⁶Re), and particulate radiopharmaceuticals labeled with radioactive dysprosium (¹⁶⁵Dy), holmium (¹⁶⁶Ho), and samarium (¹⁵³Sm) have been used successfully in people. The radioisotope used is based on the energy of the β radiation emitted and the expected thickness of the synovium.³² In a large joint with a thick synovium, deep penetration with high-energy β radiation is desirable for sufficient treatment of inflamed tissue.³³ Ferric hydroxide macroaggregate labeled with high-energy ¹⁶⁶Ho β radiation emitter (penetration depth of 3 mm in tissue) deeply ablated synovium but injured normal intraarticular and periarticular structures, resulting in edema and effusion in the treated joint. The use of lower-energy β radiation with shallower penetration may be limited to mild synovial hyperplasia but results in less periarticular soft tissue injury.³⁴ Hydroxyapatite microspheres labeled with ¹⁵³Sm β radiation emitter (penetration depth of 1 mm in tissue) were safe and effective for intraarticular administration in horses.

TABLE 90-1

Radiation Therapy for Painful Degenerative and Inflammatory Musculoskeletal Conditions in Horses

CONDITION	TREATMENT TECHNIQUE	RADIATION DOSE	NUMBER OF CASES	RETURN TO RACING (%)	REFERENCES
Osteoarthritis					
Carpus	Plesiotherapy with γ -radiation (^{222}Rn , ^{60}Co)	5-10 Gy	39	80	13, 26, 41, 42
	Plesiotherapy with γ -radiation (^{137}Cs)	12 Gy	51	84	39
	Teletherapy with orthovoltage x-rays (HVL: 0.5-1.3 mm Cu)	5-15 Gy given in 3 to 7 dose fractions	38	71	26-28
PIP joint	Plesiotherapy with γ -radiation (^{60}Co)	8 Gy	1	100	26
	Plesiotherapy with γ -radiation (^{137}Cs)	12 Gy	22	77	39
	Teletherapy with orthovoltage x-rays (HVL: 0.5 mm Cu)	4-10 Gy given in 3 to 7 dose fractions	21	62	27
MCP joint	Plesiotherapy with γ -radiation (^{222}Rn , ^{60}Co)	5-9 Gy	19	74	13, 26, 42
	Plesiotherapy with γ -radiation (^{137}Cs)	12 Gy	25	60	39
	Teletherapy with orthovoltage x-rays (HVL: 1.3 mm Cu)	12-15 Gy given in 3 dose fractions	5	40	26
Sesamoiditis	Plesiotherapy with γ -radiation (^{222}Rn , ^{60}Co)	5-9 Gy	10	80	13, 26, 41, 42
	Plesiotherapy with γ -radiation (^{137}Cs)	12 Gy	12	80	39
	Teletherapy with orthovoltage x-rays (HVL: 1.3 mm Cu)	10-12 Gy given in 3 dose fractions	4	75	26
Navicular osteitis	Plesiotherapy with γ -radiation (^{222}Rn)	4.5-9 Gy	4	50	41
	Teletherapy with orthovoltage x-rays (HVL: 1.3 mm Cu)	12-15 Gy given in 3 dose fractions	2	100	26
Villonodular synovitis	Postoperative teletherapy with orthovoltage x-rays	12 Gy given in 4 dose fractions	14	90	36
Tendonitis or Desmitis					
Suspensory ligament	Plesiotherapy with γ -radiation (^{222}Rn)	4.5-7 Gy	4	50	41
	Plesiotherapy with γ -radiation (^{137}Cs)	12 Gy	17	64	39
Digital flexor tendon	Plesiotherapy with γ -radiation (^{222}Rn , ^{60}Co , ^{182}Ta)	7-15 Gy	4	25	30, 42
	Plesiotherapy with γ -radiation (^{137}Cs)	12 Gy	7	71	39
	Teletherapy with orthovoltage x-rays (HVL: 0.5-1.3 mm Cu)	4.5-15 Gy given in 3 to 7 dose fractions	5	80	26, 28
New Bone Growth					
Splints	Plesiotherapy with γ -radiation (^{222}Rn)	4.5-9 Gy	4	50	41
	Plesiotherapy with γ -radiation (^{137}Cs)	12 Gy	20	55	39
	Postoperative plesiotherapy with γ -radiation (^{60}Co)	5 Gy	5	100	13
McIII periostitis	Plesiotherapy with γ -radiation (^{222}Rn)	9 Gy	2	100	40
	Teletherapy with orthovoltage x-rays (HVL: 0.5 mm Cu)	4-10 Gy given in 3 to 7 dose fractions	8	37	28

HVL, Half-value layer; McIII, third metacarpal bone; MCP, metacarpophalangeal; PIP, proximal interphalangeal.

CLINICAL APPLICATIONS

Irradiation was efficacious for treatment of painful degenerative and inflammatory musculoskeletal conditions in horses. The treatment goal is long-term pain relief and return to racing or performance. Although modern standards of clinical research cannot be applied to these clinical studies, the general message is a remarkable consistency in the response pattern.

Although radiation therapy should not be used indiscriminately, it should not be viewed as a last resort. Radiation therapy is effective in managing refractory, chronic stages of various degenerative disorders and should be used

for conditions that do not respond within a few months to conservative treatments, including administration of NSAIDs, local injections (corticosteroids or other anti-inflammatory products), physical therapy, and physiotherapy. Strenuous exercise should be avoided, and the horse should be given state-of-the-art physiotherapy after radiation therapy is used. General recommendations include stall rest with handwalking for 30 to 90 days and a gradual return to regular training over 60 to 90 days.

A summary of clinical results of radiotherapy for painful refractory orthopedic conditions is found in Table 90-1. Overall success rate was 60% to 70%, although data are not contemporary and techniques are different from those

practiced today. Onset and duration of analgesia were often difficult to measure. Low success rates were found in horses with chronic conditions or in those in which many unsuccessful treatments had previously been performed.

Chronic Synovitis

When synovitis plays a major role in the arthritic process, radiation therapy may be advantageous. Treatment is directed at reducing synovial inflammation and proliferation to prevent progressive joint deterioration and control of joint effusion, fibrosis, and pain. Inflamed synovium induces damage to the articular surfaces by causing effusion, up-regulation of endothelial adhesion molecules, liberation of inflammatory mediators and destructive enzymes, and alterations in the synovial fluid constituents.³⁵

Chemical, surgical, or radiation-induced synovectomy can be performed. Similar to surgical synovectomy, radiation synovectomy destroys diseased synovium, and the intent is to allow regeneration of normal synovium and amelioration of clinical signs. In people the duration of response after radiation synovectomy is related inversely to the amount of cartilage and bone destruction. These findings emphasize the importance of screening horses for radiological evidence of cartilage and bone destruction before considering radiation synovectomy. It is imperative to discriminate pain arising from inflamed synovium from that originating from cartilage or bone damage, so that horses with pain from the latter, which is likely to be unaffected by radiation synovectomy, do not undergo unnecessary treatment.

Irradiation is recommended in horses with chronic OA, after osteochondral fragment removal if synovium is proliferative, in horses with idiopathic synovitis, and potentially as an ancillary treatment for infectious arthritis. The role of radiation therapy in treating infectious arthritis is limited to preventing chronic synovitis and treating reactive arthritis. Radiation therapy should not be used until bacteria have been eliminated, because the antiinflammatory effects of radiation can exacerbate infection. In addition, radiation therapy should be limited strictly to adult horses, because the antiproliferative effects of radiation damage growing bones and joints in young horses. External beam irradiation can be used as an adjuvant to incomplete surgical synovectomy.^{36,37} Radiation doses of 7 to 10 Gy do not cause delayed wound healing or wound complications when the incision is excluded from the field of radiation. Intraarticular administration of ¹⁵³Sm may be used as a single modality when thickness of the inflamed synovium does not exceed 1 mm.^{32,38} Treatment doses ranging from 7 to 34 Gy have been found to be safe in horses.³⁸ For thicker synovial conditions the use of higher-energy radionuclides such as holmium (¹⁶⁶Ho) and rhenium (¹⁸⁶Re) may be required. Treated horses may experience transient pain (lameness), pitting edema, and effusion. In people, concomitant intraarticular injection of triamcinolone acetate prevents transient local reaction and reduces pain.

Degenerative Bone and Joint Disorders

Radiation therapy is used to treat various types of equine lameness caused by inflammatory and degenerative changes affecting bones, joints, and tendons. The most common indications for radiation therapy include chronic traumatic arthritis and OA of the carpal and fetlock joints,

sesamoiditis, active carpalitis with swelling and mild mineralization, and chronic carpalitis. Radiographic examination should be performed before radiation therapy is performed. This helps ensure that the cause of lameness is not an osteochondral fragment or another condition that is best handled surgically. The antiinflammatory and analgesic effects of radiation may stabilize the injury process in subacute and chronic painful disorders, when periarticular new bone proliferation is minimal and damage to cartilage is not obvious. Horses with joints with end-stage OA are unlikely to benefit from irradiation.²⁷ Because radiation has no inhibitory effect on the degenerative processes in OA, the treatment goal is limited to pain relief.

Radiation therapy can be used for horses with tendonitis, tenosynovitis, and desmitis. Long-term results in horses with acute and subacute conditions are better than in those with chronic conditions. In horses with chronic OA in which substantial periarticular radiological changes have occurred, radiation therapy is used to control inflammation and pain and to prevent excessive fibrosis and calcium deposition, which can result in dysfunction, reduced joint motion, and deformity. Horses with severe OA that show extensive new bone, large amounts of mineralization of soft tissues, and evidence of cartilage destruction are not treated routinely because they rarely improve enough to perform satisfactorily.

Treatment results have not been uniform because of many variables, including severity and location of the lesion, degeneration of the articular cartilage and preexisting OA, radiation dose and technique used, and duration of rest after treatment. In addition, questionable causes and pathogenesis make degenerative disorders prone to polypragmasy. Finally, the effects of enforced rest periods in the overall management are not known, which makes definitive assessment of the value of radiation therapy impossible.

The efficacy of plesiotherapy using ¹³⁷Cs packs was evaluated in 147 horses (46% Thoroughbreds, 27% Quarter Horses, and 12% Standardbreds) treated at the University of California, Davis, Veterinary Medical Teaching Hospital.³⁹ The treatment dose was 12 Gy given over 24 to 32 hours. Treatment responses were judged to be good, meaning that the horse returned to racing and was sound, or poor, meaning that the horse showed no response or the response was temporary. However, this was not a controlled study, and the results should be interpreted cautiously. Treatment was most effective for horses with carpalitis, OA of the proximal interphalangeal joint, and sesamoiditis and least effective for those with OA of the metacarpophalangeal joint and splints (see Table 90-1). Results were less favorable for treatment of horses with desmitis and tendonitis.

Because of the radiation hazard associated with the use of radioactive sources, treatments are currently done at the University of California, Davis, Veterinary Medical Teaching Hospital with a linear accelerator. Depending on the volume of the lesion to be treated and the size of the joint, irradiation is done with 4 MV (Clinac 4, Varian, Lake Oswego, Oregon, United States) or 6 MV (Clinac 2100 C, Varian) x-rays. Horses were anesthetized in a recovery stall adjacent to one of the two radiation therapy suites. Interim results in 14 horses with refractory OA of the proximal interphalangeal joint or with osteophytes associated with

mild OA followed for a minimum of 12 months after treatment indicate that irradiation is effective in controlling pain even after unsuccessful previous treatments including surgery, medical treatment, laser therapy, acoustic shock wave therapy, or ultrasound hyperthermia. Eighty-three percent of horses had a good clinical response, meaning that these horses returned to their previous performance level.

Preventing New Bone Growth

Posttraumatic exostosis occurs after repair of bone fractures (third carpal bone and third metacarpal or metatarsal bone condylar fractures) and after certain surgical procedures, such as arthrodesis and distal splint bone removal. Radiological changes are usually more advanced than are clinical signs and functional impairment. Risk factors that predispose horses to develop exostoses are not known. A history of previous new bone growth after surgery is the most substantial predisposing condition. Although a report described regression of excessive callus on a splint bone,⁴⁰ horses with painful mature exostosis or periarticular and soft tissue calcification usually do not benefit from radiotherapy except for pain relief. These horses require excision of calcified tissue followed by postoperative irradiation.

Radiation therapy is a powerful prophylactic treatment to prevent abnormal ossification in stress-related bone and periosteal injury in race horses. Treatments should be done with high-energy radiation, such as that produced by linear accelerators or telecobalt units. Doses of 8 to 10 Gy are given in a single treatment. The effective therapeutic

window reaches from a still-undefined preoperative time to about 2 days after surgery or traumatic soft tissue injury. In an ongoing prospective study conducted at the University of California, Davis, Veterinary Medical Teaching Hospital, prophylactic irradiation was given to horses at risk for developing abnormal mineralization after surgery or horses with a previous history of periarticular calcification and exostosis. A single dose of 10 Gy (1000 rad) was given using a linear accelerator immediately after surgical curettage of the excessive bony proliferation. Depending on the surgical field and the size of the joint, irradiation was done with 4 MV (Clinac 4, Varian) or 6 MV (Clinac 2100 C, Varian) x-rays. While horses were still under general anesthesia after surgery, they were moved from the operating room to one of the two radiation therapy suites for irradiation. Close proximity of the two rooms at the hospital minimized the potential for surgical and anesthetic complications during transportation. Interim results in 34 horses with carpal chip fractures (N = 10) and exostosis after trauma or splint bone fracture (N = 24) with a minimum of 12 months' follow-up after treatment indicated that irradiation was effective in long-term prevention of abnormal postoperative mineralization. Eighty-three percent of horses had a good clinical response, meaning that horses returned to previous performance level. Although subjective evaluation criteria are insufficient to define the role of radiotherapy compared with other therapies, a third of the treated horses with heterotopic ossification after previous surgical treatments had complete radiological response lasting more than 1 year.

Chapter 91

Rest and Rehabilitation

Barrie D. Grant

The number of publications about the effects of exercise on bone, cartilage, and tendons has increased substantially. The results of these investigations have allowed not only the research community but also practicing veterinarians to gain more insight into the effects of mild, moderate, and strenuous exercise on the skeletal system, especially regarding the pathogenesis of fractures and osteoarthritis. Unfortunately, results of controlled studies of the effects of deconditioning on bone, cartilage, and tendons have not been disseminated widely. Presently each clinician recommends a rest and rehabilitation program based often on intuition, anecdotal experience, and tradition. These recommendations have withstood the test of time, however, and can serve as a guide.

The number of alternative therapies and therapists has also increased. Although some benefits to this approach are possible, many of the modalities have not been tested in a

standard scientific method, and popularity often is based on the principle that alternative approaches are less expensive and have faster results.

PRINCIPLES OF REST AND REHABILITATION PROGRAMS

The following are some basic principles that should be considered when formulating a specific plan for a specific injury.

1. Is the diagnosis complete? An incomplete diagnosis and thus treatment lead to poor results. Arthroscopic removal of a carpal fracture in the apparently lame limb will have poor results if there is an osteochondral fracture in the contralateral fetlock joint. Hindlimb suspensory desmitis is unlikely to resolve satisfactorily if mild ataxia is concurrent. An expedient, complete, and accurate diagnosis affords the best chance for long-term success.
2. Horses can tolerate extensive periods of stall confinement without becoming deranged psychopaths. They do need to be in clean airy stalls, so they can see other horses, and energy intake should be reduced. Clinicians should avoid walking horses every 4 or 5 days to see how they are doing, because horses tend to find any excuse suddenly to jump or rear and may sustain reinjury.

3. The heart and muscles do not undergo any clinically significant deconditioning for at least 4 weeks after a standard anaerobic training program. Therefore many horses with minor injuries, or even a suspicion of a minor ligament or tendon problem, possibly can heal with 4 weeks of rest, with little loss in performance. The cardiac parameters actually improve 5 days after the last extensive training effort. Little will be lost and much could be gained if experienced jumping and dressage horses with lameness problems could be walked under tack for a week before major events.
4. An earlier return to training, in the form of walking under saddle, swimming, or controlled exercise on a treadmill, can reduce the chance of further injury than if a previously stall-confined horse is turned out in a paddock and allowed to run, buck, slide, and turn quickly. If paddock turnout is used, then administering sedation and gradually increasing the size of the paddock are recommended. Leaving a horse in a paddock continuously also is best once the horse has been introduced to the freedom. If a horse is stabled each evening, then it tends to buck and play again each morning when released.

REST

The basic principle of rest is to reduce the force and strain on injured tissue and allow the normal reparative processes to proceed without further insult. Muscle tissue can heal in a much shorter period than tendons or ligaments, but the repair of cartilage is accomplished by the metaplasia of replacement tissue, which takes 4 to 6 months. The quality and quantity of rest depends on the severity of the condition, the disposition of the horse, the owner, and the trainer, and their expectations.

Complete Immobilization

Although complete immobilization can be accomplished with internal fixation, external coaptation with a cast also can reduce the motion of fracture fragments and excessive strain placed on damaged ligaments or tendons. The long-term use of cast immobilization can result in osteoarthritis (fracture disease) and osteopenia. Normal joints can tolerate at least 4 weeks of cast immobilization without significant irreversible change to the articular cartilage.¹ Well-designed splints and braces offer an alternative for conditions that do not require complete rest or can be used for intermediary support in the transition from a cast to having no external support.

Stall Rest

Stall rest is the most common form of rest recommended and is highly effective as long as weekly episodes of outside activity do not interrupt it. The effects of controlled exercise on articular cartilage remain controversial. French and colleagues² concluded that early postoperative exercise is not detrimental to repair of experimentally created osteochondral defects of the carpus. Other investigators suggested deleterious effects of early exercise on the healing

of carpal osteochondral defects.³ However, exercise may be beneficial in maintaining normal concentrations of glycosaminoglycan in insulted articular cartilage.⁴ The administration of polysulfated glycosaminoglycans may have a protective effect against the deleterious results of early postoperative exercise on experimentally induced osteochondral defects.³ Only a cost-benefit investigation with a sufficient number of horses will show if the expense of the medication is justified, with an earlier return to competition compared with horses restricted to stall rest.

Owners are always concerned about the effect that enforced stall rest can have on the mental status of horses, but provided that energy intake is restricted and horses have visual contact with other horses, most adapt satisfactorily. During inactivity many horses lose muscle mass and tone, which are rapidly restored, and horses that become overweight are less likely to return to athletic competition than leaner cohorts. It is important to stress good husbandry practices, because soiled wet bedding or infrequent hoof care can lead to chronic hoof problems. I have seen many horses with joint disease develop subsolar hematomas on the opposite limb, predisposing to or because of the joint disease. These hematomas can become subsolar abscesses if the husbandry is inadequate.

Experience has shown that 60 days is the minimum amount of time necessary for the repair of soft tissues after orthopedic surgery,² but convincing eager and aggressive owners and trainers that this time is a positive economic decision is often difficult.

Reduction of Excessive Movement

In horses with severe orthopedic and neurological problems, recent improvement in slings has helped to reduce the risk of further injury from difficulties in lying down and getting up and the risk of laminitis in the contralateral limb. I prefer the Liftex sling (Liftex, Warminster, Pennsylvania, United States) to the more complicated Anderson sling (CDA Products, Potter Valley, California, United States) for everyday use, although I recognize that the Anderson sling has some features that are helpful in lifting severely injured or neurologically compromised horses. Not all horses tolerate a sling, especially those under a year of age, and further injury can possibly occur if a horse becomes violent. Giving the horse a small amount of acepromazine reduces anxiety before a sling is applied. Having a short introductory period for the first session and rewarding acceptable behavior with food is helpful. Slings are not meant to provide vertical stability to horses that cannot stand by themselves. Slings are best used to provide a method for injured horses to reduce weight bearing for short periods. Experienced horses take full weight off the limbs and sit as a person might in a hammock for short periods, two or three times an hour.

Use of crossies or overhead chains can also prevent excessive movement and force on injured areas from horses lying down and struggling to rise. Young horses may not accept this form of restraint well, which may increase the chance of injury because they fight the system. However, most Thoroughbred flat racehorses in training adapt satisfactorily. It is important to allow horses three or four sessions a day with the head down to prevent pneumonia, which can occur with improper drainage of pulmonary secretions.

Paddock Rest

After stall confinement, tradition has stressed a period of paddock rest before a horse is returned to active training. When to give paddock rest and how it is administered are based on each individual horse. The type of injury, response to treatment, personality of the horse and owners, and the season of the year are major considerations. In my experience horses can overexercise and reinjure healing tissue or incur new injuries when turned out. The use of small paddocks (6 × 6 m) to inhibit running is a suitable compromise.

The initial introduction of the horse to the paddock is the time when most mishaps can occur. Sedation, protective boots (tendons and bell or overreach boots), and avoiding muddy, snowy, frozen conditions and unfamiliar horses greatly reduce injuries. Ideally the horse should be allowed to remain in the paddock at all times, instead of being turned out each morning after a night of stall confinement. It is necessary to continue to monitor the general health care of the horse, including anthelmintic prophylaxis and immunization against respiratory pathogens that are spread easily among horses communicating over adjacent fences. Foot care is still a concern. Many horses may require shoeing to prevent abnormal hoof wear, which could result in an uneven gait when they return to active training.

Ridden Walking

After stall confinement and handwalking, I prefer to ride the horse at walk, beginning with 10 minutes a day and progressing to 30 minutes a day after 30 days, rather than using paddock exercise. This increase of activity is felt to stimulate the maturation of repair tissue in cartilage and tendons.

EXERCISE

Exercise as a basic component of rehabilitation has as its most basic goal to return an injured horse to at least its previous level of performance. The owner and/or trainer need(s) to have a realistic idea of what is possible with each type of injury and the relative severity of the injury, considering the inherent risks of each form of athletic performance. For example, for an elite dressage horse with a severe hindlimb suspensory injury, attempts to return to elite competition may well be a fool's errand, especially if the horse does not have an elite rider. The selection of an alternative form of competition, such as show jumping, that is not associated with such a high incidence of suspensory problems might suit the horse better.

There are two diverging approaches regarding the intensity of exercise used in rehabilitation. The most common is a protective program that uses the minimum amount of conditioning necessary to return a horse to competition without excessive forces and overuse. For example, a racehorse with pathology on the weight-bearing joint surfaces often has exercise limited to soft rebounding surfaces, using shock absorbing shoes and being ridden by a lighter rider, at less than maximal speeds for shorter periods. This approach has been successful but takes advantage of each horse's inherent ability to perform at a higher level of activity than it has been trained for, because horses are competitive and most want to please their riders.

Although many disciplines allow horses to perform soundly repeatedly while underconditioned, there are others such as flat and hurdle racing, eventing, and endurance disciplines that do not. From personal experience, entering and starting a horse of questionable soundness or underconditioned because of an unsoundness in a 50-mile endurance race most often results in a tired, lame, and stressed companion that must be led the last 10 miles over rough trails either in the blazing sun or cold, wet darkness. As veterinarians, owners, and trainers, we should not take advantage of our noble companions by exploiting their willingness to perform at a higher level of competition than they have been prepared for.

The opposite approach is the mindset that the injured tissue needs to be stimulated to be stronger than normal. Familiar to anyone who has gone through physical therapy after knee surgery, this is the approach used by human physical therapists. They prescribe the use of weights, Cybex machines, treadmills, and verbal intimidation to attain new levels of strength and fitness before permitting a return to standard training. In order for this method to be successful and not result in reinjury, a commitment to a longer time must be made. A recent study from Australia using the thickness of the dorsal cortex of the third metacarpal bone (McIII), as measured by serial radiography as a barometer, determined that it required a mean of over 500 days to achieve a maximum thickness. This same study also showed that a higher stress load than normal is required to stimulate the McIII to model to this degree.

Passive Exercise

Passive exercise can begin immediately after joint surgery to reduce the amount of postoperative immobility. Theoretically, passive exercise improves distribution of nutrients to chondrocytes and reduces the number of synovial adhesions to any osteochondral defects on the edge of a joint. The type of reparative tissue that develops under synovial adhesions is fibrous and not the hyaline-like material that fills a full-thickness defect when no synovial tissue has adhered to the defect.⁵ I routinely begin passive joint movement on the first postoperative day. The joint is flexed just to the position that produces discomfort 15 to 20 times twice a day, for 30 days. Passive exercise is not indicated in joints with any detectable instability or in which a problem with primary healing of the joint capsule exists.

Handwalking

Handwalking is the mildest form of active exercise and often is recommended along with stall rest. Although recommending handwalking early in the postoperative period is easy to appease owners, trainers, and caretakers, it is also essential to realize that early disruption of a primary clot in an osteochondral defect can result in poor healing of the defect.⁵ The chances of excessive and unpredictable behavior that can result in removal of the clot are increased with removing an active horse from a stall for short periods. The benefits of complete stall rest for the first 30 days far outweigh any benefit that 5 to 10 minutes of handwalking may produce. Handwalking for 5 to 10 minutes a day beginning at day 30, and gradually increasing to 30 minutes at postoperative day 60, is common practice. Handwalking seems to be the most objectionable form of exercise to

owners and caretakers, because horses act up or the potential for them to do so is anticipated and dreaded. The new form of caged horse walkers appears to be much safer and, although horses are constantly turning, this appears to be a suitable form of exercise to replace handwalking. Alternatively, ridden walking exercise can be used.

Aquatreds and Swimming

Using swimming pools and submerged treadmills (aquatreds) is still popular and at least in specific locations has withstood the test of time. Minimal controlled data are available to document the benefits of these modalities for treating horses with athletic injuries. That the cardiopulmonary system responds substantially to swimming has been documented, but only anecdotal information exists for aquatreds. Both modalities assist in increasing joint mobility and producing some physical activity in a controlled environment. The force to the axial skeleton is reduced, and this benefits horses with a nondisplaced fracture or a joint with advanced osteoarthritis. However, the reduction of the weight-bearing force in rehabilitation may not be desirable, because osteoporosis develops when training is curtailed for more than 30 days.⁶ Returning the skeletal system to its previous competitive state requires a longer time than for muscles and the cardiopulmonary system. Reconditioning the muscles by swimming or aquatreds, before reconditioning the skeletal system, increases the possibility of having horses that are too eager and able to produce more force than the bones, joints, tendons, and ligaments can tolerate. The recognition that stress fractures of the humerus are more common in horses returned to training after only 30 to 60 days of rest bears testimony to the inability of the skeletal system to adapt to the stress of training as quickly as the muscle does.⁷

High-Speed Treadmills

The increase in the number of privately owned treadmills could increase the quality of healing of horses with athletic injury. High-speed treadmills have a number of benefits for reconditioning equine athletes. The speed, distance, slope, heart rate, and climatic conditions can be controlled, monitored, and, with some systems, even programmed. Work effort can be increased with a weighted saddle and raising the slope of the treadmill, without having to increase the speed. The force on the tendons can be increased slowly by increasing the slope of the treadmill slowly.

Using treadmills for exercising horses is now accepted widely because the injury rate has been low if good judgment is used, especially when introducing a new horse. It is important to realize that training on a treadmill is not

the same as racing or training on a racing surface. Horses require twice as much work on a treadmill at maximum oxygen consumption (VO_2) to produce the same muscle changes as galloping on a training track with a rider.⁸ Horses also require speeds of at least 14 m/sec to produce the same changes on implanted strain gauges in the McIIIs as breezing on a racetrack.⁹ Some treadmills cannot achieve this speed, and lay operators often are reluctant to exercise horses at 14 m/sec because they feel the horses may become injured.

We have found little problem with long-term training on a treadmill. Horses usually trot 1000 m at 4 m/sec and then gallop for 2000 m at 10 m/sec. We have not recognized any foot problems that may result from excessive time on the treadmill,¹⁰ although the training plates are hot to the touch after a training session. A constant fine mist applied to the treadmill belt is supposed to reduce the heat. Recently it has been shown that prolonged treadmill training can result in carpal articular cartilage changes.¹¹

Active Training

The importance of periodic monitoring for any subtle clinical signs as a horse progresses through the final stages of training before competition cannot be overstated. The trainers with the most success in returning horses with athletic injuries to a successful career are those who are patient and careful observers. Horses often show signs of increased inflammation and gait abnormalities as the training intensity increases from tack walking and jogging to galloping. Reducing the amount and quality of the exercise for 30 days may be all that is necessary to reduce the inflammation, without medication.

Hill Training

It is possible to produce the same training effect by exercising horses on moderate inclines (e.g., $\frac{1}{2}$ mile at 13% incline) at a 50% reduction in the speed of horses trained on a racetrack.¹² Trotting downhill is not necessary for most conditioning programs other than endurance or cross-country eventing. Trotting downhill may lead to an increase in the incidence of proximal suspensory problems and also increases the forces on the stifle joint. I used interval training in 15 2-year-old Thoroughbreds being trained for racing, using a program consisting of three intervals, with the first at an extended trot, the second at a canter, and the third at a gallop, and found the horses had minimal unsoundness and were competitive. Walking the horses downhill allowed time to recover and kept the horses relaxed and manageable.

Acupuncture

▣ EQUINE ACUPUNCTURE FOR LAMENESS DIAGNOSIS AND TREATMENT

Allen M. Schoen

Interest in veterinary acupuncture for lameness diagnosis and treatment has increased greatly in the public and veterinary medical communities. With this increased awareness has come an increase in veterinary acupuncture research and thus a better understanding of the physiological basis of acupuncture and its clinical applications. Acupuncture may be used as an adjunct diagnostic and therapeutic tool to our traditional lameness examination and to the treatment of lameness, but it is not meant to be a substitute.

With the increased interest in equine acupuncture, there has also been additional controversy and use and misuse of this modality. It is important to understand the scientific basis, traditional Chinese medical theories, and clinical indications and limitations if acupuncture is to be used in a professional manner as part of an integrated approach to equine lameness. Currently, equine acupuncture is practiced by veterinarians trained in the Western medical perspective of scientific acupuncture and the traditional Chinese and Japanese medical theories. The approach may vary slightly based on the practitioner's perspective.

The history of equine acupuncture dates back to 2000 to 3000 BCE during the Shang and Chow dynasties in China. Around 650 BCE Bai-le wrote *Bai-le's Canon of Veterinary Medicine*, one of the first veterinary textbooks, which described acupuncture and moxibustion in equine medicine. The first atlas of equine acupuncture points and channels, *Ma Jing Kong-xiue Tu*, was written during the Sui period, from 581 to 618 CE.¹ Equine back pain was first addressed in the ancient veterinary textbook *Yuan-Heng Liao Ma Ji (Yuan-Heng's Therapeutic Treatise of Horses)*.² Periodically, anecdotal reports of using equine acupuncture would come to the Western world. The first substantial introduction occurred in the 1970s, when the International Veterinary Acupuncture Society was established and developed training programs in veterinary acupuncture in the United States. In 1996 the American Veterinary Medical Association stated, "Veterinary acupuncture and acuthery are considered valid modalities, but the potential for abuse exists. These techniques should be regarded as surgical and/or medical procedures under state practice acts. It is recommended that extensive continuing education

programs be undertaken before a veterinarian is considered competent to practice acupuncture."³ Postgraduate education in veterinary acupuncture throughout the world—including Australia, Europe, Scandinavia, North and South America, and other areas—is offered by the International Veterinary Acupuncture Society, based in Fort Collins, Colorado.⁴ The Chi Institute of Traditional Chinese Medicine in Reddick, Florida⁵; Colorado State University College of Veterinary Medicine continuing education program in Fort Collins, Colorado⁶; Tufts University School of Veterinary Medicine in North Grafton, Massachusetts⁷; and the Veterinary Institute for Therapeutic Alternatives in Sherman, Connecticut⁸ also offer postgraduate programs. All of the programs are in the United States.

SCIENTIFIC BASIS

Acupuncture may be defined in a Western medical perspective as the stimulation of specific predetermined points on the body to achieve a therapeutic or homeostatic effect. Recent research has provided evidence for the anatomical classification of acupoints. Acupuncture points are areas on the skin of decreased electrical resistance or increased electrical conductivity. Acupuncture points correspond to four known neural structures. Type I acupoints, which make up 67% of all acupoints, are considered motor points. The motor point is the point in a muscle that, when electrical stimulation is applied, will produce a maximal contraction with minimal intensity of stimulation. Motor points are located near the point where the nerve enters the muscle. Type II acupoints are located on the superficial nerves in the sagittal plane on the midline dorsally and ventrally. Type III acupoints are located at high-density foci of superficial nerves and nerve plexuses. For instance, acupoint GB-34 is located at the point where the common fibular (peroneal) nerve divides into the deep and superficial branches. Type IV acupoints are located at the muscle-tendon junctions, where the Golgi tendon organ is located.⁹ Recently, histological studies have revealed that small microtubules, consisting of free nerve endings, arterioles, and venules, penetrate through the fascia at acupuncture points (Figure 92-1).¹⁰

Acupuncture has many varied physiological effects on all systems throughout the body. No one mechanism can explain all the physiological effects observed. Traditional Chinese medical theories have explained these effects for 4000 years, based on empirical observations and descriptions of naturally occurring phenomena. Western medical theories include the gate and multiple gate theories, autonomic theories, humeral mechanisms, and bioelectric theories.¹⁰ Detailed discussions of the neurophysiological basis of acupuncture are reviewed in a number of texts.⁹⁻¹² Essentially, acupuncture stimulates various sensory receptors (pain, thermal, pressure, and touch), which stimulate sensory afferent nerves, which transmit the signal through the central nervous system to the hypothalamic-pituitary

Fig. 92-1 • Schematic drawing of the skin, showing a neurovascular bundle wrapped by a sleeve of loose connective tissue deep to an acupoint. (From Schoen AM, ed: *Veterinary acupuncture: ancient art to modern medicine*, ed 2, St Louis, 2001, Mosby.)

Fig. 92-2 • Cutaneous nerve entering the dermis at an acupuncture point along the bladder meridian. (From Schoen AM, ed: *Veterinary acupuncture: ancient art to modern medicine*, ed 2, St Louis, 2001, Mosby.)

system (Figure 92-2). The acupoints correlate with cutaneous areas containing higher concentrations of free sensory nerve endings, mast cells, lymphatics, capillaries, and venules. Various neurotransmitters and neurohormones are then released and have subsequent effects throughout the body. Research in rabbits using electroacupuncture-induced neural activation, detected by the use of manganese-enhanced functional magnetic resonance imaging, demonstrated a corresponding cerebral link between peripheral acupoints and central neural pathways. Research such as this is aiding in further understanding the effects

of local peripheral stimulation on specific areas in the brain.¹³ Electroacupuncture has also been found to stimulate endogenous opioids, vasoactive peptides, adrenocorticotrophic hormone, cortisol, and catecholamine in cerebrospinal fluid and peripheral plasma in ponies.¹⁴ Bossut and colleagues¹⁵ documented changes in plasma cortisol and β -endorphin in horses subjected to electroacupuncture for cutaneous analgesia. Changes in serum protein and blood gas concentrations also have been demonstrated in donkeys after acupuncture.^{16,17} Xie and colleagues¹⁸ documented that electroacupuncture could relieve experimental pain in the horse via the release of β -endorphin. They found that acupuncture stimulation using local acupuncture points with high frequency (80 to 120 Hz) is more effective than using distal points with low frequency (20 Hz). They found that acupoints close to the painful areas require high-frequency electroacupuncture stimulation, whereas the acupoints far from the painful areas may be stimulated with low-frequency electroacupuncture. Electroacupuncture generally is considered to have stronger effects than other types of acupuncture methods.¹⁸ The degree of stimulation appears to depend on the location of the specific acupoints.^{19,20}

Through understanding the neurophysiology and neuroanatomy of acupuncture, one can appreciate that acupuncture may stimulate nerves, increase local microcirculation to joints and muscles, relieve muscle spasms, and cause a release of various neurotransmitters. Clinically, one may see the benefits of these effects in treating equine lameness caused by soft tissue injury, muscle spasms, nerve trauma, and other conditions.

TRADITIONAL CHINESE MEDICAL THEORIES

Acupuncture has been used in China to treat equine lameness for a few thousand years. Chinese acupuncture was based on the empirical use of acupoints for certain conditions. Historically, acupuncture meridians were not acknowledged in animals. Specific empirical points based on experience were identified and named for location or function. Equine acupuncture meridians, or pathways, have been transposed onto horses from human acupuncture maps only in the past 40 years.

Traditional Chinese medicine acupuncture diagnosis and treatment are based on the pattern differentiations that are developed from two main theories of traditional Chinese medicine: the Five Element theory and the Eight Principles, which require a great deal of study.²¹ The traditional Chinese medicine diagnosis is defined as a specific pattern based on imbalances in the five elements (also called *five phases*), imbalances and disorders in specific meridians or organs, or specific patterns of disharmony. The diagnosis is based on a physical examination of the horse, including evaluation of the tongue and pulse. Tongue inspection includes evaluation of the color of the tongue, the moistness, and the color and thickness of any tongue coating. Palpation of the jugular pulse would be described as *weak*, *strong*, *wiry*, and so on. Tongue and pulse examination and an overall examination would lead to a traditional Chinese medicine diagnosis and treatment of appropriate acupuncture points. Xie²² describes a traditional Chinese medicine five-step method for diagnosis and treatment. This includes the following:

Veterinary acupuncture: ancient art to modern medicine, ed 2, St Louis, 2001, Mosby.)

- Acupuncture is the injection of various solutions into the acupuncture points. The hypodermic needle is stimulating the acupuncture point as a traditional acupuncture needle would. In addition, the solution is stimulating the pressure receptors for a period, and the solution is having its specific effect as well. Solutions injected include saline, vitamins such as B₁₂, nonsteroidal analgesics, local anesthetic solutions such as lidocaine, and occasionally homeopathic and herbal solutions, depending on the veterinarian's preference. Electroacupuncture, using a portable electroacupuncture unit, normally is used for nerve stimulation to treat severe chronic cervical, thoracolumbar, or lumbosacral problems or an affected joint, tendon, or ligament. These electroacupuncture units have electrodes attached to the acupuncture needles. Positive results with electroacupuncture have been documented for treatment of lameness in horses. Electroacupuncture decreased the lameness score in horses ($P < .001$).²⁴ Although poorly documented, electroacupuncture without needles is sometimes applied as well. Moxibustion is a form of thermostimulation using a Chinese herb, *Artemisia vulgaris*. Low-level or cold laser therapy is also used to stimulate acupuncture points. Gold implants have been used to treat navicular disease and chronic back pain and provide long-term stimulation of acupoints. This approach is an adaptation of the Chinese technique of sutures embedded into acupoints. Acupressure often is taught to the client to

administer between acupuncture treatments to potentiate the effect. Detailed descriptions of these techniques are provided by Altman.²⁵

From a Western medical perspective, acupuncture point selection is based on locating points on the body where stimulation produces a beneficial change in the central nervous system by modulating ongoing physiological activity, releasing local muscular spasms, and increasing local microcirculation. From a traditional Chinese medicine perspective, acupoints are selected based on a pattern differentiation developed from the Five Element theory or Eight Principles. The choice of acupoints based on the Eight Principles depends more on tongue and pulse findings and a comprehensive history. The Japanese approach to point selection follows a diagnostic acupuncture point examination, palpating diagnostic acupoints, including association (*Shu*) points on the dorsal aspect of the thoracolumbar region, alarm (*Mu*) points on the ventral aspect of the abdomen, and other diagnostic points. Many clinicians choose their points based on a combination of Chinese, Japanese, and Western diagnostic techniques, including tongue and pulse examination and diagnosis, diagnostic acupuncture point examination, sometimes including *Ting* points (points around the coronary band), and a comprehensive Western medical examination and history.^{26,27} The number of acupuncture points treated may vary from one to more than 20, depending on the condition treated and the approach and experience of the practitioner. The depth of needle insertion varies from 1 mm to 12 cm, depending on the location of the point, such as the coronary band versus dorsal lumbar musculature. The number of treatments required depends on the condition treated and the chronicity of the problem, usually ranging from one to eight treatments. The length of treatment varies from 5 to 30 minutes.

Manual therapies, such as chiropractic or osteopathy, are often applied along with acupuncture. They appear to work synergistically, acupuncture relieving muscle spasms and increasing circulation, chiropractic helping to correct skeletal fixations (see Chapter 93), and osteopathy affecting the fascia and skeletal structures (see Chapter 95). The combination of these therapies often leads to a more rapid response and greater efficacy, with fewer treatments required.

CLINICAL APPLICATIONS IN LAMENESS EXAMINATION AND TREATMENT

Acupuncture Diagnostic Examination

Acupuncture and manual therapies may be used diagnostically to aid in evaluating various lameness and performance problems. Acupuncture is an excellent diagnostic aid as an adjunct to a conventional lameness examination. Many of the diagnostic acupoints are located lateral to the dorsal midline, between the longissimus and iliocostalis muscles, along the acupuncture meridian known as the *bladder meridian*.²⁶ In addition, some diagnostic points are actually trigger points, knots or tight bands in a muscle. For instance, a triceps trigger point is often sensitive to palpation when a distal forelimb lameness is present and correlates with the acupoint Small Intestine 9. A triceps trigger point may not indicate exactly where the lameness

is or what the cause is, but it does indicate that something is reactive in that region (Figure 92-4).

Diagnostic acupoints also are located around the coronary band on the forelimb and hindlimb, known as *Ting* points (Figure 92-5).¹⁵ Each diagnostic acupuncture point may have four or five meanings, depending on which other points show up as reactive on the examination. For instance, one point, Large Intestine 16 (located in a depression on the cranial border of the scapula, at the intersection of the cranial margin of the scapular muscles and the caudal margin of the brachiocephalicus muscle, cranioventral to the first thoracic vertebrae) may be reactive in horses with forelimb lameness, cervical conditions, or a contralateral hindlimb lameness.²⁶ Sensitivity on acupoints along the bladder meridian, lateral to the dorsal midline, along the back may indicate that a hindlimb lameness is related to the stifle or hock, or that a primary back problem is related to the saddle fit, the rider, or a conformational problem. Sensitivity at acupoints suggesting a problem in the hock region also may be reactive with nearby injuries, such as a proximal suspensory problem. In addition, reactivity may indicate internal organ problems via a somatovisceral reflex. The combination of reactive points often aids the clinician in localizing the cause of the problem and determining a diagnosis. Often a horse may have a localized distal limb lameness along with a back problem. Sometimes acupoint diagnosis assists the veterinarian in figuring out which may have come first, the distal limb lameness or the back problem, based on the degree of sensitivity of the various points. Acupuncture diagnosis can be an excellent adjunct to conventional lameness examination, flexion tests, diagnostic analgesia, radiography, ultrasonography, and other diagnostic approaches. Not uncommonly we use all of our diagnostic capabilities, including nuclear scintigraphy and magnetic resonance imaging, and still do not arrive at a diagnosis. Acupuncture is often an excellent adjunct technique that may assist in elucidating the problem. In people, musculoskeletal pain often is accompanied by muscle shortening in peripheral and paraspinal muscles from spasms and contractures, and secondary trigger points and autonomic manifestations of neuropathies are also present in chronic musculoskeletal pain.²⁸ Patterns of trigger points distant to the primary problem, compensating for the primary musculoskeletal problem, also have been found.²⁹ These patterns are also evident in equine acupuncture lameness examinations. For instance, the horse may have a primary hock or stifle problem and may then develop compensatory patterns of trigger points in the back and neck and contralateral forelimb. These patterns show up as standard patterns of trigger points that may assist the veterinarian in the primary diagnosis.

An integrative approach to diagnosis is incorporated along with the acupuncture diagnostic palpation examination and includes evaluation of conformation, saddle fit, shoeing, and rider and training programs and the conventional lameness examination. Chiropractic evaluation, including static and motion palpation, also is included, which allows for a more comprehensive evaluation of all potential causes of lameness.

Acupuncture Therapy for Lameness

Acupuncture has been reported to be effective for treating various musculoskeletal pain-producing conditions and

Fig. 92-4 • Diagnostic acupuncture palpation points. (Courtesy Peg Fleming. From Schoen AM, ed: *Veterinary acupuncture: ancient art to modern medicine*, ed 2, St Louis, 2001, Mosby.)

Fig. 92-5 • Ting points of the equine front foot. In a lateral position the points are SI-1 and HT-9; in a medial position the points are LI-1 and LU-11. (From Schoen AM, ed: *Veterinary acupuncture: ancient art to modern medicine*, ed 2, St Louis, 2001, Mosby.)

has been found to be beneficial in treating cervical, thoracolumbar, and lumbosacral hyperpathia,^{30,31} chronic back pain, chronic lameness, osteoarthritis, and colic. Hyperpathia, increased pain sensation detected as muscle spasms and increased sensitivity of acupuncture points, is often secondary to numerous causes, including work-related muscle soreness and injuries, metabolic diseases, infectious diseases, and underlying soft tissue and orthopedic problems. Wherever possible, primary underlying causes of lameness should be explored with appropriate diagnostic procedures. Conventional and complementary therapies should be considered based on what is most appropriate for the particular condition.

Back Pain

Chronic back pain can be a major cause of poor performance and may be caused by soft tissue damage or lesions to the thoracolumbar vertebrae. Numerous studies have documented the benefits of acupuncture for equine back pain.³²⁻⁴²

Xie and colleagues²⁴ documented the success of electroacupuncture for treating chronic back pain in performance horses in a controlled clinical trial. They found that three electroacupuncture sessions were needed for clinical improvement. Conventional medical approaches, including the administration of muscle relaxants and analgesics, usually offer only temporary and minimal improvement, decreasing the clinical signs but not addressing the specific problems. Acupuncture is able to address specific muscle spasms and trigger points. Research suggests that electroacupuncture may be stronger and more effective than dry needle techniques or aquapuncture.²⁴ Clinically, aquapuncture and dry needle techniques appear to be effective.

Pain Associated with Lameness of the Distal Aspect of the Limb

Acupuncture has been reported to be beneficial in horses with various distal limb lameness⁴³⁻⁶⁵ and has been beneficial in treating lameness related to the shoulder, elbow, carpus, tarsus, fetlock, stifle, hip, and numerous soft tissue injuries. In one study evaluating acupuncture in the treatment of distal limb lameness, Xie and co-workers²⁴ found that electroacupuncture can partially relieve pain caused by the mechanical pressure induced by tightening a screw against the sole. They found that electroacupuncture significantly reduced the degree of lameness ($P < 0.001$). Electroacupuncture simultaneously increased plasma β -endorphin concentration, which suggests that endorphin release may be one of the pathways in which acupuncture relieves experimental pain. Electroacupuncture did not alter adrenocorticotrophic hormone concentrations, which indicates that the hormone may not be involved in this type of analgesia. This indicates that the mechanism of acupuncture analgesia is not merely a nerve block, as with local anesthetic solution, but that acupuncture analgesia also has central-acting effects. This correlates well with other clinical studies demonstrating the benefits of acupuncture in relieving equine lameness caused by joint contusion, muscular atrophy, rheumatic pain, and laminitis. Using a similar experimental design in a controlled clinical trial, Hackett and colleagues⁶⁵ found that acupuncture alleviated equine pain, based on heart rate measurements as an indicator of pain response. In this study acupuncture

was found to be more beneficial than nonsteroidal antiinflammatory medications.

The experience of numerous clinicians suggests that acupuncture, combining local and distant points and using various techniques, can be beneficial as a primary or secondary modality. In clinical practice, acupuncture is beneficial in resolving chronic back pain. Establishing a primary cause of back pain is critical and includes evaluating the feet, saddle fit, rider, training, and conformation. If pain primarily is caused by conformation problems, long-term resolution may include periodic electroacupuncture, traditional acupuncture, or gold bead implantation.

Acupuncture and chiropractic are used successfully in treating various equine musculoskeletal conditions as primary treatments or as adjuncts to conventional veterinary therapeutic techniques. For instance, a horse may have primary distal hock joint pain and may be treated with an intraarticular injection. However, the injection may not completely resolve hock lameness. The horse may still "not be right" or may "be off." Often secondary compensation and subsequent patterns of trigger points, muscular spasms in the longissimus, and vertebral fixations in the lumbar and cervical regions remain unresolved. Acupuncture and chiropractic therapy may then be used to treat the sequelae of the primary hock problem successfully. Hence the clinician then may resolve 100% of the lameness and increase client satisfaction.

Acupoint selection for lameness may include specific local points or *ah shi* (tender points) around a specific joint or region, points related to the secondary compensation for the primary lameness, and points based on traditional Chinese medicine or Japanese meridian therapy. Acupuncture may be used as primary therapy for distal limb lameness if conventional medical approaches have not demonstrated substantial improvement, or as an adjunct to conventional therapy. Horses with limb lameness that may benefit from acupuncture include those with laminitis; navicular disease; carpal, metacarpal, tarsal, fetlock, and pastern problems; soft tissue injuries; and some idiopathic problems. Horses with acute and chronic laminitis have responded favorably to acupuncture using dry needles, hemoacupuncture, or electroacupuncture. In the treatment of laminitis, local points around the coronary band are used along with distant points based on traditional Chinese medicine therapy.

SUMMARY

Acupuncture can be beneficial in diagnosing and treating various lameness conditions, including distal limb and back problems. A thorough conventional diagnostic examination should be conducted along with an acupuncture diagnostic examination. All therapeutic options appropriate for a specific lameness condition should be considered. The advantages and disadvantages of each therapy should be discussed. Acupuncture can be considered as a primary therapy or as an adjunct treatment, depending on the condition. No one form of medicine has all the answers. Clinicians should consider the most appropriate conventional and complementary diagnostic and therapeutic modalities for the particular horse and its owner to develop a comprehensive, integrative approach to equine lameness. Acupuncture is one of these complementary approaches that may be beneficial for the lame horse.

▣ ACUPUNCTURE CHANNEL PALPATION AND EQUINE MUSCULOSKELETAL PAIN

William H. McCormick

The key to the diagnosis and treatment of equine musculoskeletal pain with acupuncture is the Oriental examination. The preferred use of acupuncture in a healthy, nonlame sports horse implies the anticipation and rectification of abnormalities before they become clinical entities. However, in the presence of overt pathology, the descriptive methodology and therapeutic protocol of acupuncture will proceed as in a presupposed normal horse. The basic principle of Traditional Oriental Medicine (TOM) as stated in Mandarin Chinese is *bien jheng lun jhi*, or in translation, “treatment is based on pattern differentiation.”¹ The *si jhun*, or four examinations of (1) looking, (2) asking, (3) palpating, and (4) listening and smelling, are the criteria for determining patterns. A patient's pattern is defined by the sum total of the signs, symptoms, tongue, and pulse as determined by the *si jhun*.² Palpation is the most easily adapted of the four examinations for horses. In current equine practice the underpinning logic of TOM is combined with the precise palpation of the Japanese tradition and the linear analysis of Western equine lameness diagnosis.

How does the Oriental pattern-based therapy differ from the Western disease-based approach? The Western practitioner arrives at a diagnosis by physical examination supported by the available technologies such as nerve blocks, radiography, nuclear scintigraphy, and other techniques. The strict practitioner of TOM must rely on the patterns demonstrated by the horse using the *si jhun* without technical support. For example, in a horse with pain in the palmar aspect of a foot one might expect the following patterns, to name only a few: *Blood Stasis*, or fixed pain; *Qi Stagnation*, or moving, referred muscle pain; *Liver Depression*, or anger expressed in stereotypical behavior; and *Heart Qi Vacuity*, or anxiety. The total of the patterns is a description of the presentation of the disease in TOM. Most diseases exhibit a number of different patterns. Furthermore, therapy is defined by the pattern, because each pattern must be addressed in the subsequent therapeutic principles. In other words, the pattern of *Blood Stasis* (fixed pain) requires the use of a TOM therapy that will *Quicken the Blood and Resolve Stasis*. *Qi Stagnation* requires *Moving Qi*. The stated functions of each acupoint or herbal medicinal are used to determine which acupoints or medicinals to select. The proper use of the descriptive methodology of TOM forces a practitioner to describe each individual in terms of patterns that will then be used to determine therapy. None of this replaces Western structural diagnosis, but the scope of one's physical examination is greatly enhanced.

One must evaluate the use of acupuncture by the elimination of abnormal pattern(s). However, any other therapy, be it Western or Oriental, can also be evaluated in terms of its effect on the pattern(s). For the purpose of practical illustration, consider that a horse with pain in the palmar aspect of the foot is not lame, but the rider complains of a change in performance caused by pain—for example, stiff in the corners, late leaving the ground when jumping, sore

back. In such a horse the TOM pattern may add important information, whereas radiography, scintigraphy, and magnetic resonance imaging are technological overkill, expensive, unwieldy, and perhaps misleading. It may be less invasive and more efficient to treat the horse with available modalities such as shoeing, drugs, acupuncture, and herbs and to subsequently evaluate the change in pattern and performance. Sophisticated imaging techniques can and should be used to establish a structural anatomical diagnosis when possible. The therapeutic advantage of an integrated Western and Oriental approach is most applicable to a subclinically or functionally sore horse, as opposed to a horse with a structural lameness.

There is one examination within TOM that can be conducted in a timely manner and that can add information about every horse's response to musculoskeletal pathology. Channel Diagnosis is a technique by which individual acupoints are palpated to determine the characteristics of those sites. Most acupoints are linked in groups called *channels*, which allow for a systematic organization. The acupoints themselves are specific anatomical sites on the body that a practitioner can use for diagnosis and treatment (Figure 92-6).³ Usually an acupoint is in a palpable depression in regions of high electrical conductance.⁴ Although there are 173 acupoints described in the traditional veterinary literature,⁵ less than 20 diagnostic acupoints are needed for the assessment of the response of the horse to exercise.

The qualitative acupoint description attained through palpation can be useful in a Western context. Acupoint examination should include a grading system for reactivity and a recording of those reactions over time. I use the following simple grading system for acupoints in Excess. As opposed to the characteristic of Deficiency, acupoints in Excess are the easiest to appreciate and locate, because they are actively sensitive and energetically rise to meet the examiner's palpation. The grading scheme is as follows: Grade I is a normal, supple, and nonpainful response to deep (1 to 5 cm) palpation. Grade II is a slight muscle twinge that is fatigable. Grade III is consistent pain or avoidance response to deep palpation. Palpation of an acupoint with Grade IV sensitivity will elicit a sharp avoidance response accompanied by a kick or a bite. Sensitivity of Grades III and IV are of sufficient severity to warrant therapy.

The Deficiency pattern is the mirror image of the Excess pattern. Whereas the Excess pattern reflects the superficial response of the organism to adversity, the Deficiency pattern reflects a more subtle depth of pathology.⁶ Unfortunately, the determination of the presence of a Deficiency pattern requires the clinician to recognize the horse's minimal passive resistance to palpation. The Deficiency pattern can best be appreciated after the practitioner has injected intraarticular antiinflammatory medication in a degenerative joint. In such a horse the Excess pattern of muscle hyperreactivity related to the joint will be dramatically dissipated, but there will remain a low resistance that can easily be missed in superficial palpation. The sharper the Excess perceived by the examiner the greater the probability of the presence of underlying, hidden Deficiency. The difference between these two patterns in sports horses is theorized to be caused by the difference in reflex muscle tension caused by synovial receptors (Excess)

BOX 92-1

Traditional Oriental Medicine Acupoints and International Veterinary Acupuncture Transpositional Points for Best Overall Assessment of a Horse

1. Large Intestine (LI) 18: An acupoint at the level of the caudal aspect of Viborg's triangle on the ventral aspect of the sternocleidomastoid muscle at the junction of the third (C3) and the fourth (C4) cervical vertebrae. The distal course of this channel passes over the dorsomedial aspect of the distal extremity of the forelimb.^{7,8}
2. Small Intestine (SI) 16: An acupoint located caudal to the angle of the mandible in a depression on the dorsal border of the sternocleidomastoid muscle, and dorsal to the transverse processes of C3 and C4 or approximately 8 to 10 cm caudal to LI 18. Distally the SI channel courses over the dorsolateral aspect of the forelimb.^{7,8}
3. Triple Heater (TH) 15: An acupoint located on the cranial border of the scapula in a depression approximately one third of the distance from the cranial angle of the scapula to the shoulder joint. TH 15 is defined by the ventral borders of the cervical serratus and the cervical trapezius muscles. The course of this channel crosses the dorsal midline of the distal extremity of the forelimb.^{5,7}
4. Urinary Bladder (UB) 42: An acupoint located in a depression over the seventh intercostal space just caudal to the scapular cartilage in a muscular groove between the longissimus thoracis and the iliocostalis thoracis muscles, approximately 20 cm from the dorsal midline. UB 42 is the *Shu* or associated point for the Lung (LU) channel, which runs over the distal medial aspect of the equine forelimb.^{5,7}
5. Urinary Bladder (BL) 14: An acupoint that is approximately 12 cm lateral to the midline and parallel to the caudal border of the dorsal spinous process of the ninth thoracic vertebra. In the ninth intercostal space, this acupoint is situated approximately 10 cm caudal and dorsal to UB 42. UB 14 is the *Shu* point of the Pericardium (PC) channel in the IVAS (International Veterinary Acupuncture Society) transpositional system. The PC channel courses over the palmar midline of the distal aspect of the digit.^{7,9}
6. Urinary Bladder (BL) 18, *Gan Shu*: An acupoint located approximately 12 cm lateral to the caudal border of the dorsal spinous processes of the thirteenth and fourteenth thoracic vertebrae, at the thirteenth and fourteenth intercostal spaces in the muscular groove between the iliocostalis and the latissimus dorsi muscles. BL 18 is associated with the Liver channel, the distal course of which passes over the distal dorsomedial aspect of the hindlimb.^{7,10}
7. Urinary Bladder (BL) 19, *Dan Shu*: An acupoint located approximately 12 cm lateral to the caudal border of the dorsal spinous processes of the fifteenth and sixteenth thoracic vertebrae, at the fifteenth and sixteenth intercostal spaces in the muscular groove between the iliocostalis and the latissimus dorsi muscles. BL 19 is associated with the Gall Bladder channel, which courses over the dorsolateral distal aspect of the hindlimb.^{7,10}
8. Urinary Bladder (BL) 20, *Pi Shu*: An acupoint located approximately 12 cm lateral to the caudal border of the spinous process of the seventeenth thoracic vertebra, at the last intercostal space in the muscular groove between the iliocostalis and the latissimus dorsi muscles. BL 20 is associated with the Spleen channel, which crosses the distal medial aspect of the hindlimb.^{7,10}
9. *Yao Zhong*: An acupoint approximately 12 cm lateral to the dorsal midline between the third and the fourth lumbar vertebrae, midway between the caudal border of the last rib and *Shen Shu*, a traditional veterinary acupoint. *Yao Zhong* is associated with the Stomach channel, which courses over the dorsal distal aspect of the hindlimb.^{5,11}
10. *Shen Shu*: An acupoint approximately 6 cm lateral to the lumbosacral space. *Shen Shu* is the traditional veterinary acupoint associated with the Kidney channel, which courses over the plantaromedial aspect of the tarsus and the plantar midline of the distal aspect of the hindlimb.^{5,11}
11. *Xie Qi*: An acupoint in the muscular groove between the biceps femoris and the semimembranosus muscles and at a level horizontal to the anus. *Xie Qi* is used as the associated point of the Urinary Bladder channel, which courses over the plantarolateral distal aspect of the hindlimb.^{5,11}
12. *Feng Men* (Gall Bladder [GB] 20): An acupoint in a depression cranial to the wing of the atlas, 6 cm ventral to the dorsal midline and 3 cm caudal to the ear base. *Feng Men* reflects the distal dorsolateral aspect of the hindlimb.^{5,10}
13. *Fu-Tu* (BL 10): An acupoint in a depression cranial to the wing of the atlas, 6 cm caudal to the ear base and 4.5 cm ventral to the dorsal midline. *Fu-Tu* reflects the distal plantarolateral aspect of the hindlimb.^{5,10}
14. *Dan Tian* (GB 28): An acupoint in a depression 4.5 cm ventral to the tuber coxae at the origin of the tensor fascia latae muscle. *Dan Tian* reflects the distal dorsolateral aspect of the hindlimb.^{5,12}

and extrasynovial structures (Deficiency). A nonarticular example of extreme Excess and Deficiency patterns in the horse occurring simultaneously would be that of tying-up, in which the “boardlike” quality of the superficial muscles prevents any deep palpation of Deficiency in the underlying structurally affected tissues.

Each of the following acupoints corresponds to a TOM channel or meridian, which in turn is named after an internal organ. The twelve channels govern the flow of *Qi*, or life forces, for the whole body. I mix TOM acupoints with International Veterinary Acupuncture Society (IVAS) transpositional points to give the best overall assessment of a horse (Box 92-1).

What meaning can we attribute to reactive acupoints? I published a series of articles on the use of reactive acupoints in Excess for pain referable to the shoulder joint,¹² metacarpophalangeal joint,¹³ distal interphalangeal (DIP) joint,¹⁴ and the joints of the distal aspect of the hindlimb.¹⁵ These articles were based on 712 lame and “sore” horses. Over 14 years, which succeeded 13 years of strictly Western lameness practice, many thousands of examinations were conducted to establish a protocol and to subsequently

confirm the principles for evaluating reactive acupoints. In another study 350 working sports horses and racehorses were represented as serviceably sound, but 37% of the horses were lame and 39% had reactive acupoints.¹⁶ When the lame horses were compared with the sound horses with respect to reactive acupoints, 25% of the sound horses had Grade III or IV reactive acupoints, whereas 63% of lame horses had similar abnormalities.¹⁶ Therefore, reactive acupoints in the channels were frequently observed and bore a close relationship to lameness and, by implication, a similar relationship to subclinical musculoskeletal pain.

The following is a set of guidelines for palpating acupoints in Excess:

1. Palpable reactive acupoints in musculoskeletal disease are dependent on neural control through the spinal reflex (Figure 92-7).
2. Reactive acupoints that reflect the distal aspect of the limb can be differentiated from local muscular injury, somatovisceral pain, spinal neurogenic pain, and myofascial pain by intraarticular medication. That is to say, if a pattern of reactive acupoints is

Fig. 92-7 • The mediation of channel pain through the spinal reflex. (Courtesy William E. Jones.)

present and if intraarticular medication abolishes the pattern, then the treated joint(s) alone are responsible for the changed reactive acupoints regardless of what other pathology may be present. Intraarticular mepivacaine hydrochloride* will change acupoint reactivity within 10 minutes. Intraarticular triamcinolone acetonide,[†] methylprednisolone acetate,[‡] or hyaluronan[§] will change the acupoints within 24 hours.

3. In musculoskeletal extremity pain (*Bi Syndrome*), acupuncture channel reactivity in Excess reflects only synovial inflammation in the DIP, proximal interphalangeal (PIP), metacarpophalangeal, and carpal joints in the forelimbs and the DIP, PIP, metatarsophalangeal, and distal tarsal joints and the stifle in the hindlimbs. Reactive acupoints in Excess do not reflect nonsynovial pain such as subchondral bone or extraarticular structures. Reactive acupoints in Excess are frequently present as a warning or as part of a complex disease presentation, as in fetlock inflammation together with superficial digital flexor tendon pathology, or DIP joint inflammation in association with laminitis.

4. Potentially any joint can produce any pattern of reactive acupoints, but some joints have patterns that occur statistically more frequently than others, such as BL 14 reactivity in DIP joint inflammation,¹⁴ *Yao Zhong* in metatarsophalangeal joint inflammation,¹⁵ or *Yan Chi* in stifle joint inflammation.^{3,17,18} The channel that courses across the inflammatory site and the severity of inflammation will determine the reflected acupoint and the reactivity of that acupoint. For example, pain in the palmar aspect of the foot is reflected at the acupoint BL 14, which is stimulated by pericardium channel (PC) channel reactivity (see Figure 92-6). However, BL 14 can also be stimulated by palmar inflammation in the pastern, fetlock, or carpus.
5. Complex diseases are represented by a number of different patterns occurring simultaneously. The projection of reactive acupoints by inflamed synovial structures is one clinical finding that can be easily confirmed by practical Western diagnostic tests. If a careful evaluation of the acupoints was performed before a joint injection, then the effect on the acupuncture pattern can be evaluated after the injection.
6. Somatovisceral dysfunction can be reflected in the channel palpation of sports horses. The internal organs that are frequently represented are lungs,

*Carbocaine-V, Upjohn.

[‡]Depo-Medrol, Upjohn.

[§]MAP 5, Vetrepfarm.

stomach, liver, and ovary or testis. Because somato-visceral patterns tend to be more subdued than the Excess patterns of joint inflammation, the former can be obscured. Elimination of musculoskeletal patterns by joint medication can reveal the underlying somatovisceral patterns.

7. Neurogenic pain is reflected in acupoint projection from spinal structures such as the cervical and thoracolumbar facet joints, or the sacroiliac joint. Acupoints reflecting spinal pain are manifest in the associated segment as opposed to being proximally or distally projected. The grade of reactivity of these structures is more often Grade III and, as in somato-visceral pain, can be obscured by extremity pain of an equal or more severe grade. Neurogenic pain results in the muscular splinting of the spine and a loss of systemic flexibility. Some flexibility can be added back into the system by hyperextension of the joints of the distal extremities. The cost of the greater range of articular motion is joint inflammation, which is reflected in the acupuncture channels. Thus, neurogenic pain is commonly accompanied by extremity inflammation.
8. Myofascial pain in people has been well described,¹⁹ and more recently myofascial pain in the horse has been described.²⁰ However, self-perpetuating discrete myofascial trigger points palpated within a tight band of muscle are quite rare in the horse. The cleidobrachialis muscle is one of the few muscles in the horse that is amenable to the strict definition of myofascial pain.

When a horse with subclinical pain but with a multi-pattern acupoint abnormality is examined, intraarticular medication may remove one or more patterns. If a horse has acupoint examination abnormalities reflecting the extremities of both the forelimbs and hindlimbs and the distal hock joints are injected, and if, indeed, the primary source of inflammation is the tarsus, then the whole acupuncture presentation will change. But if there is concomitant involvement of the hind fetlock, stifle, or forelimb joints, then only the pattern reflecting the distal aspect of the tarsus will change. The patterns that reflect the other joints will remain the same. Nonarticular peritarsal pathology such as painful hind splints or suspensory desmopathy will not directly cause a pattern that is reflected in reactive acupoints in Excess. Rather, the Excess pattern will reflect only the distal aspect of the tarsus. Joint infection is also not reflected in Excess acupoints.

It is good practice to routinely reexamine horses that have received joint therapy or acupuncture on both day 1 and day 7. Reexamination allows for a rider or trainer's evaluation as well as a careful reassessment by the veterinarian. If the pattern is balanced and the horse is doing well, then one's efforts should be directed toward maintaining the acupuncture balance. The remaining points of low reactivity can be managed using acupuncture or manual therapy. However, if lameness or sharply reactive acupoints remain, then the basic premise of one's diagnosis must be reevaluated.

The effect of other medications and management changes can be assessed. Shoeing changes will directly affect acupuncture balance, as will the forgiveness of track surfaces and training and management regimens. It is the

responsibility of the trainer to bring the equine athlete up to the peak of fitness without going over the edge. The acupuncture examination is one of the ways that "the edge" can be defined. From the Western point of view, the presence of acupoints in Excess in musculoskeletal conditions indicates that affected joints have not been able to spontaneously recover from exercise-induced hyperflexion. Excess acupoint reactivity in joint pain is a function of highly innervated intraarticular synovial structures that are activated by the mediators of traumatic inflammation,²¹ which in turn are activated by joint hyperextension. The distribution, incidence, and severity of Excess acupoint activity depend on the spatial distribution of nociceptor sites within specific joints and the quantity and characteristics of released inflammatory mediators within those joints. Lameness is a function of a much broader range of pain perception.

Joints that project reactive acupoints vary according to the horse's use. Thoroughbred racehorses have a greater incidence of synovial inflammation in the metacarpophalangeal joint, reflecting the proximal dorsal aspect of the proximal phalanx versus the DIP joint, whereas the converse is true for show hunters. In both types of horses I find a high incidence of distal hock joint pain. Steeplechase horses and show jumpers have a high incidence of hind fetlock inflammation, and numerous ipsilateral joints can be involved. It is difficult to determine multiple joint inflammation if lameness is not severe enough to abolish using diagnostic analgesia. Careful examination of horses after joint therapy and over time should reveal changes in acupoint reactivity. Horses returning to competition after a long rest tend to revert to the same acupuncture patterns that they displayed during previous training. In horses recovering from surgery, the acupuncture pattern is a sensitive early sign of a need for changes in management.

Two papers published in English define the limits of acupuncture in sports horses. Martin and Klide's work on back pain showed the efficacy of modulation of muscle tension on the performance of equine athletes.²² Steiss showed that acupuncture in foot lameness was no better than that expected in untreated controls.²³ Martin and Klide were treating the TOM pattern of *Qi Stagnation* or abnormal muscle tension as opposed to Steiss's fixed pain pattern of *Blood Stasis*. The strength of acupuncture is its ability to restore normal physiological activity in the face of functional abnormality. Hackett, Spitzfaden, and May showed that pain modulation after digital electroacupuncture is similar to that provided by phenylbutazone therapy.²⁴ However, foot pain cannot be as easily reversed as abnormal back muscle tension. Acupuncture can be used effectively as an adjunctive therapy if muscle hyperactivity is part of the pattern. Careful examination of the channels should provide evidence of patterns with a good therapeutic potential.

The basis of acupuncture diagnosis and therapy in musculoskeletal disease depends on pattern differentiation. The patterns most easily determined by the Western practitioner involve the precise palpation of key acupoints in Channel Diagnosis. Acupoint reactivity of musculoskeletal dysfunction is a reflection of the body's response to intraarticular trauma. Because only highly innervated synovial structures of a small number of joints of the extremities are reflected by reactive acupoints, the primary disease may be

reflected only indirectly or not at all. However, abnormal patterns are extremely common and are worth investigating regardless of the type of therapy contemplated. At the least, the abnormal pattern is a warning. The ease that one has in elimination of a pattern over time will give an idea of the persistence and severity of the underlying traumatic pathology.

The pattern projected by synovial structures is a protective mechanism, the presence of which is the teleological function of limitation of joint excursion. Therefore,

effective treatment must go beyond the elimination of acupoint imbalance and address all the underlying problems as well. Because disease in TOM consists of all of the existent abnormal patterns, treatment of multipattern abnormalities must be undertaken. In my experience the channel approach to horses with subclinical pain is effective and useful. With the exception of lameness from muscle tension, acupuncture is generally not sufficient by itself to address lameness that is obvious enough to abolish using diagnostic analgesia.

Chapter 93

Chiropractic Evaluation and Management of Musculoskeletal Disorders

Kevin K. Haussler

MANUAL THERAPY AND CHIROPRACTIC

Manual therapy involves the application of the hands directly to the body, with the goal of treating soft tissue injuries or articular dysfunction. Chiropractic, osteopathy, massage therapy, therapeutic touch, and certain physical therapy techniques are considered forms of manual therapy. Chiropractic is a health profession concerned with the diagnosis, treatment, and prevention of disorders of the musculoskeletal system and the effects of these disorders on the nervous system and general health.¹ The word *chiropractic* is derived from the Greek words *cheir*, meaning "hand," and *praktikos*, meaning "concerning action." The goal of chiropractic is to optimize health through the inherent healing ability of the body (i.e., homeostasis) as affected by and integrated through the nervous system.² The practice of chiropractic focuses on the relationship between structure (primarily the spinal column) and function (as coordinated by the nervous system) and how that relationship affects the preservation and restoration of health. Chiropractic uses controlled forces (i.e., adjustments), which are applied to specific joints or anatomical regions, to induce therapeutic responses through induced changes in joint structures, muscle function, and neurological reflexes. Research in people demonstrated reductions in pain and muscle hypertonicity and increased joint range of motion after chiropractic treatment.^{2,3}

Joint mobilization and manipulation are two types of induced articular movements used in musculoskeletal rehabilitation to restore joint function. Mobilization is characterized as repetitive joint movements induced within the normal physiological range of joint motion (Figure 93-1). Joint manipulation (e.g., chiropractic adjustment) occurs within the parapsychological zone, which lies outside of the active (i.e., patient induced) and passive ranges of joint

motion. In people, joint mobilization and manipulation induce different physiological responses. Manipulation in people relieved adjacent spontaneous myoelectrical activity immediately, whereas mobilization did not.²

PRACTITIONER QUALIFICATIONS

Equine practitioners have seen a proliferation in the use of chiropractic techniques on horses, in one form or another. Veterinarians currently do not receive any formal education in chiropractic principles or techniques; therefore many equine clinicians do not have a basic understanding of chiropractic principles or clinical applications. Conversely, chiropractors (doctors of chiropractic) do not have any formal training in comparative anatomy, physiology, or pathology or clinical equine experience. Veterinary medicine, for the most part, has been forced to acknowledge the use of chiropractic and other nontraditional modalities by horse owners who have sought practitioners who use these techniques and have experienced their perceived therapeutic effects.⁴ However, limited research has been done to evaluate the clinical effectiveness of chiropractic techniques in horses. If veterinarians have not taken the time or made the effort to learn more about these nontraditional techniques, objectively evaluating the use of chiropractic, discussing the indications or contraindications for a specific treatment modality, or applying these techniques clinically is difficult. Therefore owners often seek advice about alternative therapies or treatment from

Fig. 93-1 • Schematic representation of the three articular zones of joint motion: physiological, parapsychological, and pathological. The elastic barrier and the anatomical limit mark the transitional boundaries among the three articular zones.

someone who is not their regular veterinarian and often without his or her knowledge. To complicate matters, many laypersons claiming to be equine chiropractors are not professionally trained or licensed in chiropractic or veterinary medicine. These lay practitioners often have a limited knowledge of equine musculoskeletal anatomy, physiology, biomechanics, and pathology. Because of the potential misapplication, chiropractic evaluation and treatment should be provided only by licensed professionals (i.e., veterinarians or chiropractors working under the direct supervision of a veterinarian) who have pursued additional postgraduate training in animal chiropractic principles and techniques. The primary organizations in North America currently involved in training and certifying veterinarians and chiropractors in animal chiropractic are Options for Animals, based in Wellsville, Kansas; Parker College of Chiropractic in Dallas, Texas; and the Healing Oasis Wellness Center in Sturtevant, Wisconsin and in Canada. An additional course on equine osteopathy is offered at the Vluggen Institute in San Marcos, Texas. Equine manual therapy courses in Europe include Focus on the Equine Spine in the Netherlands; McTimoney College of Chiropractic in England; the International Academy of Veterinary Chiropractic in both Germany and England; and a Healing Oasis Wellness Center-sponsored course in Germany.

Most state chiropractic and veterinary medical boards do not allow chiropractors to treat animals unless they are working under the direct supervision of a veterinarian. This requires that the veterinarian and chiropractor work together in evaluating and treating the horse and provide appropriate follow-up care as indicated. It is strongly recommended that owners and referring veterinarians seek out licensed professionals (veterinarians or chiropractors) who have had specialized training and experience in chiropractic evaluation and treatment of horses. Veterinarians who have not pursued formal postgraduate training are not qualified to provide chiropractic care and risk producing more harm than potential benefit. It is a good idea to ask equine chiropractors about their professional and postgraduate training or certification, horse experience, and the types of techniques that they use (i.e., hands only versus more aggressive techniques, or the use of additional instruments). Chiropractic and osteopathy require a working knowledge and understanding of vertebral anatomy, physiology, biomechanics, pathology, and rehabilitation. Combining the knowledge and expertise of the veterinary and chiropractic professions provides practitioners with new insights and methods for diagnosing and managing horses with select vertebral or musculoskeletal disorders. A similar multidisciplinary approach has developed in human medicine in the last 20 years to address chronic pain syndromes and vertebral column disorders.

HISTORY OF EQUINE CHIROPRACTIC

Chiropractors often have been asked to treat the horses of clients who have experienced the benefits of chiropractic care for their own back or neck problems. Horse owners often want the opportunity to have the same type of care for their horses, without the potential adverse effects of medications or surgery. The recent increased awareness of the prevalence and management options to address back problems with which traditional veterinary medicine has

had difficulty in dealing has also stimulated horse owners' interest in complementary forms of treatment.⁵ Any vertebral column disorder can have serious effects on a horse's ability to perform. Back problems can be classified into three basic types of injuries—those involving the muscles, tendons, and ligaments (soft tissue injuries); bones and joints (osseous injuries); or nervous system (neurological disorders). However, several concurrent injuries have been reported in 17% of horses with back pain.⁶ Diagnosis of the underlying vertebral pathological conditions in horses with back pain is important for the appropriate treatment and management of these disorders (see Chapter 52).

Many horses in which chiropractic may be useful often have a history of a traumatic event or an injury related to overexertion.⁷ Trauma may occur as a single event (i.e., macrotrauma), such as a trailer accident, flipping over backward, or substantial falls over jumps. Severe musculoskeletal injuries may improve gradually, but they never resolve totally, or debilitating arthritis or soft tissue fibrosis may subsequently develop. Chronic overuse injuries (i.e., microtrauma) usually are associated with poor saddle fit, improper riding techniques, inadequate shoeing, or faulty conformation. Long periods of confinement, inconsistent training programs, or cumulative stresses and strains related to prolonged, high-level athletic activities also may predispose horses to musculoskeletal injuries and reduced performance. Older horses, like elderly people, are susceptible to loss of vertebral column flexibility, joint degeneration, and loss of muscle strength. Aged horses also have increased healing times and increased chances of having chronic conditions or abnormal musculoskeletal compensations from prior injuries. Chiropractic techniques have helped identify and treat some of these previously undiagnosed or poorly managed problems in horses. Most veterinarians use chiropractic techniques to complement their conventional veterinary practice.

COMPLEMENTARY APPROACHES

Prevalence of back problems in horses varies greatly (from 0.9% to 94%), depending on the specialization or type of practice surveyed: general practice, 0.9%; Thoroughbred racehorse practice, 2%; veterinary school referrals, 5%; mixed equine practice including dressage, show jumpers, and eventing, 13%; spinal research clinic, 47%; and equine chiropractic clinic, 94%.⁸ Clinicians often have difficulties when dealing with horses with no obvious localized pain or vague, unspecified lameness. Neck or back problems and limb injuries often are interrelated. Distal limb injuries can cause an alteration in carriage of the affected limb and altered gait, which subsequently can overwork or injure proximal limb musculature and the paraspinal musculature. Similarly, vertebral column injuries can produce gait abnormalities, increased concussive forces, and distal limb lameness. The diagnostic dilemma facing clinicians is to decide whether the limb or the vertebral column is the primary or initial cause of the horse's clinical problem. Unless the primary cause of the neck or back pain is identified and treated, most horses will have recurrent back pain when returned to work after a period of rest or a trial of antiinflammatory medications. Nonspecific back pain most likely is related to a functional impairment and not a structural disorder. Therefore many back problems may

be related to muscle or joint dysfunction, with secondary soft tissue irritation and pain generation.⁹

Chiropractic provides expertise in evaluating vertebral column disorders and can provide an additional means of diagnosis and early treatment options in certain types of gait abnormalities or performance problems. Prepurchase examinations using chiropractic examination techniques can help identify horses that have chronic underlying neck or back problems.⁷ Chiropractic addresses subclinical conditions or abnormal biomechanics, which may progress to future debilitating musculoskeletal injuries. Chiropractors are trained in using physiotherapy modalities, strength training exercises, massage, stretching techniques, and other forms of musculoskeletal and nerve rehabilitation. Equine chiropractic is a complementary modality that can be used in veterinary medicine for the diagnosis, treatment, and potential prevention of select musculoskeletal disorders in horses. However, although a few recent studies have investigated the short-term effectiveness of chiropractic intervention in the horse, none have addressed performance benefits, long-term efficacy, and the safety or cost-effectiveness of chiropractic procedures in equine veterinary medicine.

PATHOPHYSIOLOGY AND MECHANISMS OF ACTION

The vertebral motion segment is the functional unit of the vertebral column and includes two adjacent vertebrae and the associated soft tissues that bind them together. The basic elements of joint dysfunction include altered articular neurophysiology, biochemical alterations, pathological conditions of the joint capsule, and articular degeneration.^{2,3} Vertebral segment dysfunction (i.e., chiropractically defined subluxation) is a vertebral lesion characterized by the following:

1. Asymmetrical or loss of normal joint motion (Figure 93-2)
2. Diminished pain thresholds to pressure in the adjacent paraspinal tissues or osseous structures
3. Abnormal paraspinal muscle tension
4. Visual or palpatory signs of active inflammation or chronic tissue texture abnormalities (e.g., edema, fibrosis, hyperemia, or altered temperature)²

Numerous theories have been proposed and tested over the years to explain the causes of vertebral segment dysfunction in people and its effects on the neuromusculoskeletal system.^{2,3} The chiropractically defined vertebral

subluxation complex is a theoretical model that incorporates the complex mechanical and biochemical interactions of injured nervous, muscular, articular, ligamentous, vascular, and connective tissues.¹⁰ The theory of a "bone out of place" is outdated and not supported by current spinal research in people.

The goal of chiropractic treatment is to reduce pain and muscle hypertonicity, restore joint motion, and stimulate neurological reflexes. The exact mechanisms by which chiropractic techniques produce therapeutic effects are not certain. Chiropractic treatment may reduce musculoskeletal pain by stimulating nociceptive reflexes and release of neuropeptides (i.e., endorphins and enkephalins).^{2,11,12} Concurrent muscle spasms restrict joint motion and may contribute to the further development of joint stiffness. In people, palpatory changes in osseous symmetry after manipulation often are associated with soft tissue alterations and not actual reduction of an articular misalignment.⁹ Chiropractic care can improve restricted joint motion and may reduce the associated harmful effects of joint immobilization.^{2,3} In response to chronic pain or stiffness, new movement patterns are learned by the nervous system and adopted in an attempt to reduce pain or discomfort. Long after the initial injury has healed, adaptive or secondary movement patterns that predispose additional joints or muscles to injury may persist.⁹ Chiropractic treatment is thought to affect mechanoreceptors (i.e., Golgi tendon organ and muscle spindles) to induce reflex inhibition of pain and reflex muscle relaxation and to correct abnormal movement patterns.^{10,12} Additional modalities used to address altered movement patterns in people and horses include stretching or relaxing hypertonic muscles, strengthening weak muscles, and reeducating movement patterns.⁹

Successful chiropractic treatment requires specific techniques and psychomotor skills.³ A thorough knowledge of vertebral anatomy and joint biomechanics is required for proper chiropractic evaluation and treatment. Joint manipulation often induces a palpable release or movement of the restricted articulations. An audible cracking or popping also may be heard during chiropractic treatment as the applied force overcomes the elastic barrier of joint resistance.^{13,14} The rapid articular separation produces a cavitation of the synovial fluid.¹⁵ Radiological studies of synovial articulations after manipulation in people have shown a radiolucent cavity within the joint space (i.e., vacuum phenomenon) that contains 80% carbon dioxide and lasts for 15 to 20 minutes. A second attempt to recavitate the joint will be unsuccessful and potentially painful until the intraarticular gas is reabsorbed (i.e., refractory period).

Fig. 93-2 • Diagram of patterns of normal and altered joint range of motion. Symmetrical joint hypomobility is characterized by generalized stiffness. Asymmetrical joint hypomobility is characterized by reduced joint mobility in one or more directions (e.g., left lateral bending).

EQUINE CHIROPRACTIC RESEARCH

The focus of recent equine manual therapy research has been on assessing the clinical effects of chiropractic techniques on relieving pain, improving flexibility, and restoring spinal motion symmetry. A veterinarian's ability to physically induce movement in a horse's back has been questioned. Pilot work in three horses that were instrumented with spinal transducers attached to Steinman pins implanted into dorsal spinous processes at adjacent vertebrae demonstrated that manually applied forces associated

with chiropractic techniques were able to produce substantial segmental spinal motion.¹⁶ The induced spinal motions were usually beyond the normal range of segmental motion that was measured during treadmill locomotion (up to 227% larger segmental spinal range of motion induced by high-velocity, low-amplitude thrusts than measured at the walk). The next logical research question would be what, if any, are the therapeutic effects of these induced spinal movements? In two randomized, controlled clinical trials, pressure algometry was used to measure mechanical nociceptive thresholds (MNTs) in the thoracolumbar region and to evaluate whether chiropractic treatment can reduce back pain (or increase MNTs) relative to findings in a control group of horses.^{17,18} The first study evaluated 24 horses in active exercise, with the treatment group receiving high-velocity, low-amplitude thrusts applied to the thirteenth thoracic vertebra (T13) to the sixth lumbar vertebra (L6) region.¹⁷ At 2 weeks, 21 of 29 (72%) treated sites had increased MNTs, six (21%) sites had decreased MNTs, and two (7%) sites had similar MNTs. Although MNTs in all 10 treated sites within the T13 to L6 region increased, magnitude was significant in only 7 (24%) sites when compared with the control group. In the second study 38 horses without previously recognized clinical signs of back pain were randomly divided into five treatment groups with MNTs measured at seven bilateral sites at the T9 to second sacral (S2) vertebral levels.¹⁸ Single applications of instrument-assisted (Activator) high-velocity, low-amplitude thrusts and massage therapy were given at day 0 in two groups at sites of pain, muscle hypertonicity, or stiffness. Phenylbutazone was given orally at a dose of 2 g twice a day for 7 days in the third group, and active and inactive horses were assigned to two control groups. MNTs were measured at Days 0, 1, 3, and 7. The Day 7 median MNTs had increased by 27% in the chiropractic group, 12% in the massage therapy group, and 8% in the phenylbutazone group, with less than 1% changes in both control groups.¹⁸ Future research is recommended to evaluate long-term effects and the potential synergistic effects of combined therapies (e.g., chiropractic and massage therapy) for treating back pain.

Additional studies assessed the effects of equine chiropractic techniques on passive spinal mobility (i.e., flexibility) and longissimus muscle tone.^{19,20} The first study used 10 horses to objectively measure vertical displacement, applied force, and stiffness at five thoracolumbar intervertebral sites in an experimentally induced back pain model using a randomized, crossover study design.¹⁹ The chiropractic treatment induced a 15% increase in vertical displacement and a 20% increase in applied force, compared with control measurements, indicative of increased spinal flexibility and increased tolerance to applied pressure. The second study measured changes in muscle tone and electromyographic (EMG) activity within the longissimus muscle immediately after spinal manipulation or reflex inhibition therapy, compared with a control group.²⁰ Significant decreases in muscle tone and EMG activity were measured in both treatment groups, compared with no significant changes within the control group. Additional studies are needed to determine how long the increased flexibility and reduced muscle tone persist in horses treated with chiropractic techniques and whether these therapies can improve performance.

The last two studies document the potential beneficial effects of chiropractic treatment on spinal movement patterns in horses with documented back pain.^{21,22} In a dressage horse with back pain and severe loss of performance, objective spinal kinematic assessment was performed before and up to 8 months after the last chiropractic treatment.²¹ A right lateral bending restriction (functional scoliosis) was diagnosed, and two high-velocity, low-amplitude treatments were applied, 3 weeks apart. Symmetry of spinal movement indices improved dramatically after the first chiropractic treatment and remained improved above baseline at 8 months after the last treatment. It was concluded that manipulation had a measurable influence on kinematics of the thoracolumbar spine; however, this improvement was not judged equivalent to clinical improvement. A follow-up study assessed limb and spinal kinematics before and 1 hour and 3 weeks after chiropractic treatment in 10 horses.²² Significant changes in spinal kinematics were noted at the walk and trot, but no changes were noted in limb kinematics. The main overall effect was more thoracic region flexion, a reduced inclination of the pelvis, and improvement of the symmetry of the pelvic motion pattern. It was concluded that chiropractic treatment elicited slight but clinically significant changes in thoracolumbar and pelvic kinematics and that changes may be beneficial.

CLINICAL EVALUATION

Chiropractic, like any medical evaluation, begins with a thorough history, discussion of the chief complaint, and observation of the horse from a distance for conformation, posture, and signs of lameness. Chiropractic evaluation and treatment are not a substitute for a thorough lameness examination and diagnostic workup, because many horses have musculoskeletal conditions that are identified readily and managed with traditional approaches. In veterinary medicine, many structural abnormalities of the vertebral column are becoming easier to diagnose with newer imaging modalities (e.g., scintigraphy and ultrasonography). Currently most clinicians are not well educated or experienced in procedures required to perform a thorough functional evaluation of the equine vertebral column. Therefore horses with conditions not diagnosed readily using traditional modalities, or with suspected concurrent neck or back problems, may require referral for chiropractic evaluation.

Horses with conditions that may be responsive to chiropractic care have a variety of nonspecific or vague problems (Box 93-1). The focus of the chiropractic examination is placed on evaluating static and dynamic characteristics of the musculoskeletal system. Initially the horse's general attitude and behavior are monitored for signs of pain or discomfort. Vertebral column conformation then is evaluated for proper alignment and symmetry, with special attention to the top line, shape and height of the withers, and osseous pelvic symmetry. A short-coupled horse is thought to have a higher incidence of osseous disorders, whereas a long-backed horse is more prone to soft tissue injuries.²³ Conformation is a structural relationship of body segments, whereas postural analysis deals more with functional relationships. The horse is made to stand on a hard, level surface and is evaluated for a preferred or shifting

BOX 93-1

Potential Clinical Indications for Chiropractic Evaluation and Treatment of Horses

Poor performance
 Back or neck pain
 Reduced neck or back flexibility
 Not able to raise or lower head and neck
 Localized muscle tightness
 Vague lameness
 Uneven or asymmetrical gait
 Recent change in spinal conformation
 Difficult or improper saddle fit
 Discomfort with saddle placement
 Resentment of tightening of the cinch or girth
 Stiff and slow to warm up
 Bucking or pinning ears when ridden
 Lameness only when ridden
 Constantly on one rein or line
 Difficulty with a lead or gait transition
 Refusing jumps
 Resisting collection
 Difficulty with turning in one direction
 Consistent stumbling or toe dragging
 Muscle mass asymmetry
 Pelvic asymmetry
 Not standing squarely on all limbs
 Difficulty standing for the farrier
 Holding tail to one side
 Resentment of being groomed
 Behavior or avoidance problem

Modified from Willoughby SL: *Equine chiropractic care*, Port Byron, IL, United States, 1991, Options for Animals Foundation.

stance, head and neck carriage, vertebral curvatures, and muscular symmetry. Chiropractic gait analysis focuses on evaluating regional vertebral mobility and pelvic motion symmetry, in addition to the typical assessment of forelimb and hindlimb lameness. Gait analysis may help to rule out distal limb disorders and to rule in vertebral dysfunction, although limb lameness has been reported in about 85% of horses with back problems.²⁴ Motion asymmetries, restricted vertebral or pelvic mobility, not tracking straight, and lack of propulsion are a few characteristics that are evaluated. Tape on the tubera coxae or vertebral column midline may make subtle motion asymmetries easier to see. Normal vertebral column motion consists of small cumulative amounts of segmental motion, which produce an overall smooth curve or movement of the vertebral column (Figure 93-3). Evaluation of the horse's response to having a saddle placed and being ridden is important for a complete assessment of horses with back problems. Inspection of the tack for proper use and fit is always suggested on initial examination. Saddles and restraint devices should be evaluated for proper fit, padding, and positioning on the horse.

A thorough physical examination is used to eliminate other, more common causes of lameness or neurological disorders. Chiropractic evaluation focuses on evaluating and localizing segmental vertebral dysfunction, which is

Fig. 93-3 • Diagram of normal segmental vertebral contributions to overall vertebral column mobility during active left and right lateral bending. Note the smooth vertebral curve produced by cumulative segmental joint motion.

characterized by localized pain, muscle hypertonicity, and reduced joint motion.¹⁰ Palpation is used to localize and identify soft tissue and osseous structures for changes in texture, tissue mobility, or resistance to pressure.^{23,25} Soft tissue layers are evaluated from superficial to deep in two ways: by increasing digital pressure and by shifting attention with discrete palpatory movements. Shapes of structures, transitions between structures, and attachment sites also may be palpated.⁹ Soft tissue texture and mobility can be compared among the skin, subcutaneous tissue, thoracolumbar fascia, and muscle. Response to palpation is important, especially in evaluating tenderness or hypersensitivity. Osseous palpation involves evaluating osseous structures for pain, morphology, asymmetries, and alignment. Many horses with dental problems or malocclusion have localized pain during palpation of the temporomandibular joints and hypertonicity of the adjacent muscles of mastication. Osseous asymmetry of the space between the ramus of the mandible and the lateral wing of the atlas (first cervical vertebra) can be identified in horses with upper cervical congenital malformations, in horses with poll trauma caused by pulling back or falling over, or in some horses that head toss. Such asymmetry can also be seen in some otherwise clinically normal horses. The apices of the thoracic and lumbar spinous processes are readily palpable in most horses, unless they are grossly overweight. The dorsal apices of individual spinous processes are palpated with firm manual pressure, while monitoring for a localized pain response or muscle hypertonicity, indicative of local injury or impinged spinous processes. Palpable deviations of individual spinous processes are common, but usually they are not associated with spinous process fracture or vertebral malposition (i.e., bone out of place), as is commonly thought. Overlapping or malaligned dorsal spinous processes are often caused by spinous process impingement, developmental asymmetries in the neural arch, or isolated dorsal spinous process deviation of unknown cause.^{5,26} During induced kyphosis, the abaxial borders of each individual thoracolumbar spinous process and the overlying supraspinous ligament are palpated for pain, thickening, or deviation from midline. The tubera sacrale are palpated for height asymmetries and evaluated for a localized pain response to manual pressure applied dorsally or during abaxial compression. The apices of the sacral spinous processes (of the second to fifth sacral vertebrae) are palpated for pain or deviation from midline.

Fig. 93-4 • Diagram of segmental vertebral motion during manually induced left lateral bending of the vertebral column. Arrows indicate direction of applied forces to vertebral column. **A**, Normal segmental motion of the vertebral column. **B**, Locally restricted vertebral motion involving two vertebrae. **C**, Regionally restricted vertebral motion involving several vertebrae.

A complete musculoskeletal examination includes assessment of active and passive ranges of joint motion for all axial and appendicular articulations. Active joint range of motion is evaluated during induced vertebral movements (carrot stretches) and gait analysis. Assessment of passive range of motion requires muscular relaxation as the articulations are moved passively throughout the individual joint ranges of motion (Figure 93-4). Abnormal segmental vertebral motion is detected when joint motion is asymmetrical or restricted bilaterally (see Figure 93-2). Causes of segmental vertebral motion restrictions include capsular fibrosis, effusion, and inflammation. Regional causes of vertebral movement restrictions may include periarticular soft tissue adhesions, musculotendinous contractures, or, more commonly, protective muscle spasms. Combining the evaluation of joint range of motion and the presence or absence of pain at the extremes of joint motion, diagnostic interpretations can be implied.²⁷ Normal joint motion is painless, suggesting that articular structures are intact and functional. Normal joint mobility that has a painful end range of movement suggests that a minor sprain of the associated articular tissues is present. Painless joint hypomobility suggests that a contracture or adhesion is present. Painful hypomobility suggests the presence of an acute strain with secondary muscle guarding. Painless hypermobility of an articulation may indicate a complete rupture, whereas painful hypermobility suggests a partial tear of the evaluated structure.

Motion palpation is used to evaluate each vertebral segment for loss of normal joint motion and overall resistance to induced motion (see Figure 93-4; Figure 93-5). Vertebral segments with altered motion palpation findings can occur with or without localized muscle hypertonicity and pain. Using palpation to evaluate the musculoskeletal system requires an understanding of how joint motion is assessed.⁹ Moving an articulation from a neutral position first involves evaluating joint motion that has minimal and uniform resistance. As the articulation is moved toward the end range of motion, a gradual increase in the resistance to movement occurs (i.e., elastic barrier) (see Figure 93-1). End range of motion starts when any change in resistance to passive joint movement is palpable. The elastic barrier is evaluated by bringing the articulation to tension and

Fig. 93-5 • Demonstration of motion palpation with induced left lateral flexion of the thoracolumbar vertebral column.

applying gentle, rhythmic oscillations to qualify the resistance to movement. The normal joint end feel is initially soft and resilient and gradually becomes more restrictive as maximal joint range of motion is reached. This elastic barrier marks the end of physiological joint movement. A pathological or restrictive end range of motion is palpable earlier in passive joint movement and has an abrupt, restrictive end feel compared with normal joint end feel. The goal of palpating joint movement is to evaluate the initiation of motion resistance, the quality of joint motion and end feel, and the overall joint range of motion. Joint movement beyond its normal anatomical limits is characterized by ligamentous or articular capsule disruption and joint subluxation.

Individual vertebral segments are evaluated for altered motion palpation findings in flexion and extension (Figures 93-6 and 93-7); right and left lateral flexion (see Figures 93-4 and 93-5); and right and left rotation. In a relaxed horse the articulations of the individual second to sixth cervical vertebrae are assessed for the presence or loss of the normal elastic barrier during combined lateral flexion and rotation. The articulation between the fourth and fifth cervical vertebrae seems to be commonly affected in most performance horses, presumably because of locally altered biomechanical influences. The individual spinous processes of the third to twelfth thoracic vertebrae are deviated manually from midline, while monitoring for signs of reduced vertebral motion, localized pain, and induced muscle hypertonicity. Horses with poorly fitting saddles (e.g., tree too narrow) resent motion palpation of the affected vertebrae. The remaining thoracolumbar region is assessed in lateral bending and flexion and extension for similar signs of joint dysfunction. While the clinician stands next to the

Fig. 93-6 • Diagram of segmental vertebral motion during manually induced extension of the vertebral column. Fig. 93-7 • Demonstration of motion palpation with induced extension of the thoracolumbar vertebral column.

horse, segmental vertebral motion in lateral bending is assessed with one hand lying over the intervertebral articulation to be evaluated. The other hand is placed at the tail head and is used to induce rhythmic oscillations to the caudal vertebral column. Normal lateral bending is maximal at the midthoracic vertebral region and gradually diminishes toward the lumbosacral junction. Conversely, flexion and extension are minimal in the thoracic region and gradually increase until the lumbosacral junction, the site of maximal flexion and extension. Segmental vertebral motion in flexion and extension requires the clinician to be on an elevated surface to induce ventrally directed rhythmic oscillations to the intervertebral articulations of the thirteenth to sixteenth thoracic vertebrae. The sacroiliac joints are evaluated for motion restriction or pain during induced joint motion, with an applied force directed ventrally over the tuber coxae, or during abaxial compression of the tubera sacrale (see Chapter 51). The caudal vertebrae are assessed by manipulation of individual vertebrae or by application of axial traction. The range of motion of the individual forelimb and hindlimb articulations also are evaluated in flexion and extension, internal and external rotation, abduction and adduction, and circumduction

for signs of reduced joint motion, localized pain, and induced muscle hypertonicity. Palpation of the entire musculoskeletal system, including joint motion assessment of the axial and appendicular skeleton, can be accomplished within 15 to 20 minutes.

A neurological examination is indicated to evaluate horses with back problems to rule out traumatic, infectious, and toxic causes (see Chapter 11). Postural reactions also help to assess the proprioceptive status, which may be compromised in horses with certain vertebral column disorders. Rectal palpation is a commonly forgotten diagnostic test in horses with back problems. Osseous palpation rectally is useful for evaluating fractures, pelvic canal symmetry, and lumbosacral or sacroiliac joint osteoarthritis (OA). Externally induced pelvic motion during rectal palpation helps to assess lumbosacral joint motion internally. Palpation of the iliopsoas muscles for pain, swelling, or asymmetry is also important in evaluating horses with back pain. An orthopedic examination commonly is indicated to rule out or identify concurrent limb problems. Hematological evaluation, diagnostic analgesia, muscle biopsies, or cerebral spinal fluid analysis may be required in certain horses before chiropractic assessment and treatment. Imaging modalities that may contribute to a definitive diagnosis in horses with neck or back problems include radiography, myelography, ultrasonography, scintigraphy, computed tomography, and thermography. A thorough diagnostic workup and a definitive diagnosis, when available, are important for tailoring the appropriate chiropractic treatment and rehabilitation program. Horses with developmental osseous abnormalities, cervical vertebral fractures, thoracolumbar impinged dorsal spinous processes, equine protozoal myelitis, and sacroiliac joint luxation have been referred to me for chiropractic consultation. It was critical that these horses be properly diagnosed and that inappropriate chiropractic treatment not be applied, especially as the sole or primary therapeutic modality.

INDICATIONS FOR CHIROPRACTIC CARE

Chiropractic provides additional diagnostic and therapeutic approaches that are not currently available in veterinary medicine. The principal indications for equine chiropractic evaluation are acute or chronic neck or back pain, localized or regional joint stiffness, poor performance, and an altered gait that is not associated with overt lameness (see [Box 93-1](#)). Musculoskeletal conditions that are chronic or recurring, are not diagnosed readily, or do not respond to conventional veterinary care also may be indications for chiropractic consultation. A thorough diagnostic workup is required to identify soft tissue and osseous pathological conditions, neurological disorders, or other lameness conditions that may not be responsive to chiropractic care. Horses with a localized limb lameness or diagnosed neurological disease are better treated with conventional veterinary medicine. However, if a residual lameness continues or a secondary vertebral column disorder (e.g., stiffness or asymmetry) is identified, then concurrent chiropractic care is indicated. Horses that have concurrent hock pain (e.g., OA) and a stiff, painful thoracolumbar or lumbosacral vertebral region are best managed by using a multidisciplinary approach of concurrent medical treatment of the hock OA and chiropractic evaluation and treatment of

the back problem. Most horses respond favorably to concurrent management, and owners appreciate a complete and thorough medical evaluation and treatment. Similarly, horses with chronic forelimb lameness often have compensatory pain and stiffness in the withers region, which are readily addressed with chiropractic or physical therapy techniques.

The primary clinical signs that equine chiropractors assess are areas of localized musculoskeletal pain, muscle hypertonicity, and restricted joint motion. This triad of clinical signs can be found in a variety of horses with distal limb disorders, but it is most evident in those with neck or back problems. In general, localized pain, reduced vertebral segment motion, and local muscle spasms in the vertebral column are indications of a primary spinal disorder. In contrast, regional or diffuse pain, generalized stiffness, and widespread muscle hypertonicity are indications of a chronic or secondary spinal disorder, and further diagnostics should be done to identify the primary cause of lameness or poor performance. Chiropractic care may provide symptomatic relief in horses with early vertebral OA if related to joint hypomobility and subsequent immobilization degeneration. Research suggests that spinal manipulation also may affect certain visceral disorders (e.g., cardiovascular, respiratory, and gastrointestinal) through somatovisceral reflexes in animals and people.^{2,3} However, consistent and predictable long-term changes in visceral disorders rarely occur with chiropractic treatment in people or horses.

Specially trained veterinarians or chiropractors, with advanced training and experience in equine chiropractic techniques, should be able to evaluate vertebral column disorders and determine if the condition will respond to chiropractic care, if further diagnostic evaluation is required, or if the horse would be better managed with traditional veterinary care. Unfortunately, equine chiropractors often are asked to treat horses as a last resort, when all else has failed or the disease has progressed to an irreversible condition. Chiropractic care has helped some of these horses with chronic conditions when other types of conventional treatment have failed. However, chiropractic is usually much more effective in the early stages of clinical disease versus end-stage disease, where reparative processes have been exhausted. Chiropractic care and other holistic modalities often fail when used as a last resort.

CONTRAINDICATIONS

Chiropractic is not a cure-all for every back problem and is not suggested for treatment of horses with fractures, infections, neoplasia, metabolic disorders, or nonmechanically related joint disorders. Horses with serious diseases requiring immediate medical or surgical care need to be treated by conventional veterinary medicine before any chiropractic treatment is initiated. However, chiropractic care may contribute to the rehabilitation of most horses postoperatively, or those with medical conditions, by helping to restore normal musculoskeletal function. Chiropractic care usually is contraindicated in horses with acute stages of soft tissue injury. However, as the soft tissue injury heals, chiropractic has the potential to help restore normal joint motion, thus limiting the risk for future reinjury.⁹ Acute episodes of pain associated with OA, impinged

dorsal spinous processes, and severe articular changes, such as joint subluxation or luxation, are often contraindications to chiropractic care. All horses with neurological diseases should be evaluated fully to assess the potential risks or benefits of chiropractic treatment. Cervical myelopathy occurs because of structural and functional disorders in the cervical vertebrae. Static compression caused by malformation and dynamic lesions caused by vertebral segment hypermobility are contraindications to cervical manipulation. However, adjacent hypomobile vertebrae may require chiropractic treatment to help restore joint motion and reduce biomechanical stresses in the affected vertebrae. Chiropractic care cannot reverse severe degenerative processes or overt pathological conditions.

CHIROPRACTIC TECHNIQUES

Most of the current knowledge about equine chiropractic was borrowed from chiropractic techniques, theories, and research used in people and adapted to horses. Therapeutic trials of chiropractic manipulations often are used because knowledge is limited about the effects of equine chiropractic. Chiropractic addresses mechanically related disorders of the musculoskeletal and nervous systems and provides a conservative means of treatment and prevention for horses with back problems. Chiropractic treatment uses an applied, controlled force to a specific anatomical region or osseous structure to produce a desired therapeutic response. Chiropractic manipulations are applied to areas of vertebral segment dysfunction. The condition of the horse is monitored closely as the neuromusculoskeletal system responds to the applied treatment. The applied treatment influences joint, muscle, and nerve function via mechanical and biological mechanisms.² The therapeutic dosage of the applied chiropractic manipulation is modified by the number of vertebrae treated, the amount of force applied, and the frequency of treatment. The goal of chiropractic care is to restore normal joint motion, stimulate neurological reflexes, and reduce pain and muscle hypertonicity. Comparisons of sensitivity to palpation, muscle tone, and joint motion are made before and after treatment to evaluate the response to chiropractic treatment.

Clinicians and clients often ask, how can a 500-kg horse be treated with chiropractic techniques? The answer is one vertebral segment at a time. Recent equine chiropractic research has demonstrated that forces applied to instrumented vertebral segments do induce substantial vertebral motion, usually beyond the normal range of segmental motion that occurs during locomotion.¹⁶ Segmental vertebral motion characteristics induced during chiropractic treatment in horses are similar to those reported in people.²⁸ In a relaxed horse, the mass (i.e., vertebral segment) that is affected by the rapidly applied force is proportionately smaller than the mass of the clinician applying the treatment. However, if the horse does not relax the paraspinal musculature, then the mass that is affected increases dramatically from the mass of a few vertebral segments to the mass of the entire vertebral region, or potentially the entire horse. Effective joint mobilization or manipulation cannot be applied to a nervous, tense horse without risk of injury to the horse or the clinician. Chiropractic treatments in horses usually are done without any sedation or other medications, but they may occasionally be done with the

horse under general anesthesia, or coupled with intraarticular injections, if indicated.²⁹ Typical indications for manipulation in people under anesthesia include chronic myositis or fibrosis, or acute musculoskeletal pain, where reflex muscle spasms prevent a thorough assessment or impede manipulative treatment. Untrained professionals who do not have a thorough understanding of joint physiology, vertebral anatomy, or chiropractic principles resort to overly aggressive and forceful means of applying an external force (e.g., mallets and 2×4 s). Small, rapidly applied manual forces are easier to control and have a lower risk of soft tissue or bone injury than more forceful types of manipulation. A good rule of thumb is that if the procedure does not look like something that the practitioner would be willing to have done to himself or herself, then the procedure should not be done to a horse.

Horses are usually held by a trained handler on a loose lead during chiropractic treatment. The cervical vertebrae, sacrum, and extremities are evaluated and manipulated as needed from ground level. However, the thoracolumbar vertebrae and pelvis often require an elevated surface on which to stand for effective manipulation and proper positioning of the clinician (see Figure 93-7). Equine chiropractic is physically demanding and requires substantial mental concentration. The clinician and the horse must be relaxed and focused on each other. Environmental distractions are counterproductive to effective chiropractic care. Muscle relaxation allows evaluation of the elastic barrier of the joint. Motion palpation is used to evaluate joint motion restrictions so that the manipulative thrust can be applied correctly. Stabilization of adjacent joints or vertebral segments is required for proper joint manipulation.

Typically, an immediate reduction in pain and an increase in segmental vertebral motion are noted. Most horses also have increased muscle relaxation, but other therapies (e.g., acupuncture or stretching) often are used with chiropractic treatment to completely resolve any remaining muscle hypertonicity. In general, horses with conditions with an acute onset respond rapidly, whereas those with chronic conditions usually require longer treatment or rehabilitation. Horses with acute pain or vertebral column trauma may require initial antiinflammatory medication, physiotherapy modalities (e.g., ice), or rest before chiropractic treatment. If stiffness, local muscle hypertonicity, or pain remain, then two or three chiropractic treatments may be indicated. Horses with chronic neck or back stiffness may require monthly evaluation and treatment for several months' duration. Owners often request chiropractic evaluation at the beginning of the performance season or a few days after athletic competition or as a general assessment of the overall musculoskeletal system. Similarly, horses may benefit from chiropractic treatment several days before an event. Because of ethical considerations or possible masking of musculoskeletal dysfunction, it is not recommended that chiropractic treatment be performed immediately before or during any competition.

Posttreatment recommendations for actively training horses usually include stall rest or pasture turnout for one day, which provides an opportunity for the musculoskeletal system to respond to the applied treatment without immediate reexposure to potential inciting factors of the vertebral segment dysfunction. The horse returns to normal work the next day, unless other musculoskeletal injuries

are present, for which appropriate care is recommended. If stiffness or soreness is noted after chiropractic treatment, then an additional day of rest is suggested.

COMPLICATIONS OR ADVERSE EFFECTS

Potential adverse effects from properly applied chiropractic treatments include a transient stiffness or worsening of the condition after treatment (e.g., aggravated clinical signs, worsening of preexisting state, regional soreness, or lameness).³ Adverse reactions from properly applied vertebral manipulation are typically uncommon, but they may occur immediately after treatment or insidiously within 6 to 12 hours. The undesired effects usually last less than 1 to 2 days and resolve without concurrent medical intervention. If increased or acute musculoskeletal dysfunction or lameness is noted after chiropractic treatment, then a thorough reexamination and appropriate medical treatment or physiotherapy should be pursued. If the condition does not improve with conservative care, referral for more extensive diagnostic or therapeutic modalities is recommended. Potential harmful side effects from improperly applied manipulation from untrained individuals may include permanent articular damage or loss of function (e.g., torn ligaments, injured muscles, luxated joints, fractures, or possible paralysis if a severe underlying pathological condition is present).

ADJUNCT RECOMMENDATIONS AND PROGNOSIS

Chiropractic care often is supplemented with massage, physiotherapy modalities, and stretching or strengthening exercises to help soft tissue rehabilitation and to help restore normal vertebral joint motion (see Chapter 94). These concurrent therapies also help to encourage owner participation in the healing process and provide close monitoring of the horse's progress. Other recommendations may include changes in training schedules or activities, corrective shoeing, or tack changes. Horses with poorly fitting saddles often have localized pain and muscle hypertonicity in the caudal withers region. Saddle refitting, coupled with chiropractic treatment of the painful withers region, leads to rapid recovery and management of a common problem for many horse owners. In one instance a horse with a 6-month history of consistently resenting saddle placement and bucking the owner off was treated chiropractically and the next week won 11 ribbons at the local country fair. Many horses with repetitive-use disorders may benefit from cross-training activities. Clinicians report synergistic therapeutic effects with the combined use of chiropractic, acupuncture, and other holistic modalities in horses. In general, horses with conditions with an acute onset respond rapidly and have a good prognosis for return to function. Horses with chronic injuries may gain only short-term improvement of restricted motion, pain, or muscle hypertonicity. This corresponds to current research on joint immobilization and spinal learning.⁹ Horses with chronic conditions usually require a series of treatments to effect a more lasting improvement. Musculoskeletal health depends on movement and use. Scientific evidence suggests that long-term rest and inactivity are contraindicated for back problems in people.

SUMMARY

A thorough knowledge of equine vertebral anatomy, biomechanics, and pathology is required to understand the principles and theories behind chiropractic and to apply its techniques properly. Because of its potential misuse, spinal evaluation and manipulative therapies should be provided only by specially trained veterinary clinicians or licensed manual therapists. Anecdotal evidence and clinical experience suggest that chiropractic is an effective adjunct modality for the diagnosis and conservative treatment of select musculoskeletal-related disorders in horses. Recent

research including randomized, controlled clinical trials supports the efficacy of equine chiropractic techniques for reducing pain, improving flexibility, reducing muscle tone, and improving symmetry of spinal kinematics. Additional studies are needed to monitor the long-term changes and improvements in performance. Chiropractic provides additional diagnostic and therapeutic means that may help equine clinicians to identify and treat select musculoskeletal disorders. Chiropractic provides specialized evaluation and treatment of joint dysfunction and conservative treatment of neuromusculoskeletal disorders that currently lack treatments in traditional veterinary medicine.

Chapter 94

Electrophysical Agents in Physiotherapy

Amanda Sutton and Tim Watson

Electrotherapy has been a component of physiotherapy practice since the early days, but its delivery has changed remarkably and continues to do so. All electrotherapy modalities involve the introduction of some physical energy, which brings about one or more physiological changes that are used for therapeutic benefit. To appropriately select the most suitable modality, it is necessary to:

1. Determine the nature of the problem to be addressed
2. Establish the physiological changes that need to take place
3. Select the modality that is most able to bring about the changes in the tissue(s) concerned
4. Choose the appropriate dose
5. Apply the treatment

ELECTROTHERAPEUTIC WINDOWS

The effectiveness of electrotherapeutic treatment is influenced by a number of factors, including the time after the injury at which treatment is applied, the "dose" administered, the amplitude or strength applied, and the frequency. An energy delivered at a particular amplitude has a beneficial effect, whereas the same energy at lower amplitude may have no demonstrable effect. Laser therapy provides a good example—one level will produce a distinct cellular response, whereas a higher dose may be destructive. A modality applied at a specific frequency (pulsing regimen) may have a measurable benefit, whereas the same modality applied using a different pulsing profile may not achieve equivalent results.

THERAPEUTIC ULTRASOUND

Ultrasound (US) is a form of mechanical energy, not electrical energy, and therefore, strictly speaking, is not

electrotherapy but falls into the group of electrophysical agents.¹ Mechanical vibration at increasing frequencies is known as sound energy. In children and young adults, the normal audible sound range is 16 Hz to 15,000 to 20,000 Hz. Higher frequencies are known as US. The frequencies used in therapy are typically between 1.0 and 3.0 MHz (1 MHz = 1 million cycles/sec).

Sound waves are longitudinal waves consisting of areas of compression and rarefaction. When exposed to a sound wave, particles of a material oscillate about a fixed point rather than move with the wave itself. Any increase in the molecular vibration in a tissue can result in heat generation; thus US can be used to produce thermal changes in the tissues, although current therapeutic usage does not focus on this phenomenon.^{1,2} The vibration of the tissues may also have nonthermal effects. As the US wave passes through the tissue, the energy levels within the wave decrease as energy is transferred to the tissues.¹

Therapeutic Ultrasound Waves

US waves are characterized by frequency, wavelength, and velocity. Frequency is the number of times a particle experiences a complete compression/rarefaction cycle in 1 second. The wavelength is the distance between two equivalent points on the waveform in the particular medium. In an "average tissue," the wavelength at 1 MHz is 1.5 mm and at 3 MHz is 0.5 mm. The velocity is the speed at which the wave (disturbance) travels through the medium. In a saline solution, the velocity of US is approximately 1500 m/sec compared with approximately 350 m/sec in air (sound waves can travel more rapidly in a denser medium). The velocity of US in most tissues is thought to be similar to that in saline.

These three factors are related but are not consistent for all types of tissue. Typical average therapeutic US frequencies are 1 and 3 MHz, although some machines produce additional frequencies (e.g., 0.75 and 1.5 MHz), and the "long wave" US devices typically operate at 40 to 50 kHz, a much lower frequency than "traditional US" but still beyond human hearing range.

Ultrasound Waveform

The US beam is not uniform and changes in its nature with distance from the transducer. The US beam nearest the treatment head is called the near field. The behavior of the US waves in the near field is not regular, and areas of

interference and energy can be many times greater than the output set on the machine (up to 12 to 15 times greater).

Ultrasound Transmission through the Tissues

Tissues present impedance to the passage of sound waves. The specific impedance of a tissue is determined by its density and elasticity. For the maximal transmission of energy from one tissue to another, the impedance of the two tissues needs to be as similar as possible. An air gap between the generator and the skin will result in the majority of the US energy being reflected rather than transmitted to the underlying tissues.

Coupling media, water, various oils, creams, and gels, are used to bridge the air gap. Ideally, the coupling medium should be fluid so as to fill all available spaces, be relatively viscous so that it stays in place, have an impedance appropriate to the media it connects, and allow transmission of US with minimal absorption, attenuation, or disturbance. At present, the gel-based media appear to be preferable to the oils and creams. Water is a good medium and can be used as an alternative. The addition of active agents (e.g., antiinflammatory drugs) to the gel is widely practiced but remains incompletely researched.

Studies^{3,4} have considered the effect of animal hair on the transmission of US to the underlying tissue and report that best penetration is achieved by clipping the hair. In addition to the reflection that occurs at a boundary because of differences in impedance, there will also be some refraction if the wave does not strike the boundary surface at 90 degrees. Essentially, the direction of the US beam through the second medium will not be the same as its path through the original medium; its pathway is angled. The treatment head is ideally placed perpendicular to the skin surface (i.e., at 90 degrees). If the treatment head is at an angle of 15 degrees or more from the perpendicular to the plane of the skin surface, the majority of the US beam will travel through the dermal tissues (i.e., parallel to the plane of the skin surface) rather than penetrate the tissues as would be expected.

Care of the Machine

The US treatment head should be cleaned with an alcohol-based swab between treatments to minimize the potential transmission of microbial agents between horses.⁵

Contraindications

- Do not expose either an embryo or fetus to therapeutic levels of US by treating over the uterus during pregnancy
- Malignancy (DO NOT treat over tissue that is or may possibly be malignant; however, an area from which a malignancy was removed can be treated)
- Tissues in which bleeding is occurring or could reasonably be expected (typically within hours of injury)
- Substantial vascular abnormalities
- The eye
- The cardiac area in advanced heart disease
- Active physes in young foals

Precautions

US should be used at the lowest intensity, which produces a therapeutic response, in a continuous mode, moving the

applicator throughout the treatment (speed and direction are not issues). The US machine should be regularly calibrated.⁶

Treatment Record

Records should be maintained of the machine used, the machine settings (frequency, intensity, time, and pulse parameters), the area to be treated (size and location), and any immediate or untoward effects.

Absorption and Attenuation

The absorption of US energy follows an exponential pattern: more energy is absorbed in the superficial tissues than in the deep tissues.^{7,8} Thus as the US beam penetrates further into the tissues, a greater proportion of the energy has been absorbed; therefore there is less energy available to achieve therapeutic effects. The half value depth represents the depth in the tissues at which half the surface energy is available and is different for each tissue and US frequency. Tissues with high protein content are greatest absorbers of US energy. Those with higher water and low protein content absorb little. This is very important when electing US as a suitable modality.¹ It is impossible to know the thickness of each tissue layer in an individual horse; therefore average half value depths are used for each frequency: 3 MHz = 2.0 cm; 1 MHz = 4.0 cm. Tissues with absorption are tendon, ligament, fascia, joint capsule, and scar tissue. In cartilage and bone, a majority of US energy striking the surface is likely to be reflected.⁷⁻⁹

Therapeutic Effects of Ultrasound

The therapeutic effects of US are influenced by the treatment parameters chosen and are commonly divided into thermal and nonthermal.

Thermal

Therapeutic US may produce heat,¹⁰ especially in periosteum, collagenous tissues (ligament, tendon, and fascia), and fibrotic muscle. If the temperature of the damaged tissues is raised to 40 to 45° C, there is hyperemia, which may be therapeutic and help resolve chronic inflammation.¹¹ However, nonthermal effects are probably more important.

Nonthermal

The nonthermal effects of US are from cavitation and acoustic streaming.^{7,12} Cavitation, the formation of gas-filled voids within tissues and body fluids, occurs in two types—stable and unstable—which have different effects. Stable cavitation occurs at therapeutic doses of US and is the formation and growth of dissolved gas bubble accumulation. The “cavity” acts to enhance the acoustic streaming phenomena. Unstable (transient) cavitation is the formation of bubbles at the low pressure part of the US cycle. These bubbles then collapse very quickly, releasing a large amount of energy that is detrimental to tissue viability. However, this does not occur at therapeutic levels if good technique is used.

Acoustic streaming is a small-scale eddying of fluids near a vibrating structure such as cell membranes and the

surface of a stable cavitation gas bubble and affects diffusion rates and membrane permeability.¹¹ Sodium ion permeability is altered, resulting in changes in the cell membrane potential. Calcium ion transport is modified, which in turn leads to an alteration in the enzyme and cellular secretions.

The result of the combined effects of stable cavitation and acoustic streaming is that the cell membrane becomes “excited” (up-regulates), thus increasing the activity levels of the whole cell. The US energy acts as a trigger for this process, but it is the increased cellular activity that is in effect responsible for the therapeutic benefits of the modality.^{1,2,13}

Some US machines offer variable time: typical pulse ratios are 1:1 and 1:4. In 1:1 mode, the machine offers an output for 2 ms followed by 2 ms of rest. In 1:4 mode, the 2-ms output is followed by 8-ms rest period.

Ultrasound Application in Relation to Soft Tissue Repair

The process of tissue repair is a complex series of cascaded, chemically mediated events that lead to the production of scar tissue.

Inflammatory Phase

US induces the degranulation of mast cells, causing the release of arachidonic acid and its subsequent cascade.^{9,13} Thus therapeutic US is proinflammatory rather than anti-inflammatory. The benefit of US may not be to “increase” inflammation, although if applied too intensely at this stage, it is a possible outcome; rather, US should act as an “inflammatory optimizer.”¹ The inflammatory response is essential for effective tissue repair, and the more efficient the process, the more effectively it can advance to the next phase (proliferation). Studies have failed to demonstrate an antiinflammatory effect of US, and results suggest US is ineffective.¹⁴ US may be effective at normalizing inflammatory events and may have therapeutic value in promoting overall repair.^{1,7}

Proliferation

During the proliferative phase (scar production), US is pro-proliferative and stimulates (cellular up-regulation) fibroblasts, endothelial cells, and myofibroblasts.^{1,9} US may maximize efficiency, producing the required scar tissue in an optimal fashion. Low-dose pulsed US increased protein synthesis and enhanced fibroplasia and collagen synthesis.¹⁵⁻¹⁷ Recent work has identified the critical role of numerous growth factors in relation to tissue repair, and there is some evidence for an effect of US on growth factors and heat shock proteins.^{13,17}

Remodeling

During the remodeling phase of repair, the somewhat generic scar is refined such that it adopts functional characteristics of the tissues that it is repairing. Remodeling involves reorientation of the collagen fibers¹⁸ and a change from predominantly type III to more mature type I collagen. Therapeutic US increases tensile strength and scar mobility by enhancing collagen fiber orientation and the collagen profile change from type III to type I.¹⁹ US enhances functional capacity scar tissue.¹⁹

Other Applications of Therapeutic Ultrasound

Ultrasound for Fracture Repair

The application of very low-dose US over a fracture (whether healing normally, delayed, or nonunion) can be of benefit, but the effective “dose” is lower than most therapy machines can deliver. Higher-intensity US over a fracture can initiate a strong pain response, a property that may be helpful to locate stress fractures.¹

Ultrasound at Trigger Points

US can be used to stimulate acupuncture trigger points with measurable benefit.²⁰

PULSED ELECTROMAGNETIC FIELD THERAPY

Wires carrying an electric current produce a surrounding magnetic field. The magnetic field around a long straight wire is in the form of concentric circles around the central wire. When a current flows in a circular coil, an electromagnetic field is induced. A pulsed electromagnetic field (PEMF), which is emitted from an applicator, is transmitted through the tissues and is absorbed in those of low impedance (muscle and nerve), which are highly vascular, and tissues in which there is edema, effusion, or recent hematoma.²¹ PEMF therapy may have beneficial effects on damaged tissue cells, particularly at the cellular level.

Normal healthy cells have a selectively permeable membrane.²² When membrane integrity is lost through disease, chemicals that would otherwise not enter the cell can now enter, drastically lowering the voltage potential across the cell. The application of a PEMF to affected cells may restore cell membrane potential, transport, and ionic balance by either a direct ionic transport mechanism or an activation of various pumps (sodium/potassium).^{23,24} PEMF therapy is important in the inflammatory phase and reduced healing time after oral surgery in people.²⁵ PEMF therapy may reduce pain.

Bone is a calcified collagenous structure and can develop a piezoelectric potential on its external and internal surfaces. Most studies have failed to show PEMF therapy significantly improves bone remodeling.²⁶ A small but statistically significant effect of PEMF stimulation on cancellous bone graft incorporation was found in a small study (eight ponies), but missing data prohibit drawing any strong conclusions.²⁷

The clinical effects of PEMF therapy, US, and laser are all similar; the key difference in clinical use relates to where the energy is absorbed rather than the effects achieved.²¹ They have little or no effect on normal cells because “abnormal” cells respond to lower energy levels than normal cells.²¹ US is better absorbed by dense collagen-based tissues and laser by superficial vascular tissues, whereas PEMF therapy is absorbed primarily in wet, ionic, low-resistance tissues such as muscle, nerve, areas of edema, hematomas, and effusion.

Primary Effects of Pulsed Electromagnetic Field Therapy

The primary effects of PEMF therapy include²⁸:

1. Increased number of white cells, histiocytes, and fibroblasts in a wound
2. Improved rate of edema dispersion
3. Promotion of absorption of hematoma

4. Reduction (resolution) of the inflammatory process
5. Prompting a more rapid rate of fibrin fiber orientation and deposition of collagen
6. Promotion of collagen layering at an early stage
7. Stimulation of osteogenesis

PEMF therapy in the equine market consists mainly of either full-body rugs to target the tissues of the body, back, and neck, or paired coils that are strapped or bandaged to a limb.

CONTRAINDICATIONS

- Pregnancy
- Bleeding
- Severe circulatory compromise or deficit including ischemic tissue
- Physes in growing foals

LASER THERAPY

Low-level laser therapy (LLLT) is popular in people and animals. Laser is an acronym for *light amplification by the stimulated emission of radiation*. Laser light differs from ordinary light in that it is highly amplified and nondivergent. It forms part of the electromagnetic spectrum.²⁹ High-power lasers (>10 W) are commonly used surgically but are not discussed here.³⁰ Low-power lasers (<500 mW, <35 J/cm²) are used in the management of pain, wound healing, and soft tissue injury.³¹

Biophysics of Laser

Light wavelengths between 600 and 1300 nm are typically used with laser therapy.³² This includes both visible light and the near part of the infrared spectrum. Laser differs from other radiation in its unique properties of monochromaticity (single wavelength), coherence (waves in phase), and collimation (waves in parallel).²⁹ However, there exists some debate as to the necessity of such expensive properties, especially coherence.³³ Superluminous diodes, lacking the property of coherence, are also used therapeutically.³¹ Superluminous diodes (660 and 870 nm) are equally effective in stimulating fibroblast proliferation as coherent, laser light (820 nm).

The lasing medium determines the wavelength emitted, and media such as helium neon (HeNe, 632.8 nm), gallium arsenide (GaAs, 904 nm), and gallium–aluminum–arsenide (GaAlAs, 820 nm) are used clinically.³³ When used, the laser beam is scattered, reflected, transmitted, or absorbed.³² The magnitude of each depends on the application technique, the nature of the tissue being treated, and the wavelength of the incident light.³⁰ Given the low irradiation level used, the effects are likely to be photochemical because there is no appreciable temperature increase.³²

When applying LLLT, energy density (J/cm²) is an important recorded value, and ranges of 0.1 to 4 J/cm² and 1 to 10 J/cm² are used.^{29,32} However, some advocate values as high as 30 J/cm².³¹

Because penetration is wavelength dependent, an infrared beam (wavelength, 800 to 900 nm) penetrates further than a visible red beam (wavelength, 600 to 650 nm).³¹ As a result, visible red laser light is used to treat wounds and skin conditions, whereas infrared laser light is used for deeper conditions.^{29,31}

Energy density (J/cm²) is measured at the skin surface, but energy density applied to deep target tissues is unknown because of the exponential tissue absorption of the energy and uncertainty about penetration depth.²⁹ Longer wavelengths penetrate further than shorter wavelengths.^{33,34} However, actual penetration and energy density at a target site can only be speculated. Hair and skin pigmentation may adversely influence penetration.

Laser therapy is used widely in animals,³⁵ and 50% of UK veterinary surgeons surveyed in 1993 were aware of it.³⁶ Of animal physiotherapists surveyed, 64% used laser therapy, which equaled the number using US therapy.³⁷ Although LLLT has gained popularity during the past 20 years,³¹ acceptance is hampered by a paucity of supportive studies using standard research protocols,^{38–40} and there are both advocates³⁰ and detractors.⁴¹ In a randomized controlled clinical trial, LLLT had a significant pain-relieving effect, reduced joint swelling, and caused an objective improvement in hand function in people with rheumatoid arthritis.⁴²

LLLT in Veterinary Medicine

LLLT may be used in the treatment of nerve compression, bruising, wounds, tendon and ligament injuries, edema, and for pain relief.^{35,43–46}

Clinical Applications

In cell cultures, LLLT wavelengths of 660 and 870 nm (non-coherent) and 820 nm (coherent) encouraged macrophages to release factors that stimulate fibroblast proliferation and thus promote healing.³³ LLLT reduced experimentally induced inflammation by 20% to 30%.^{47,48} In vitro experiments showed an effect of laser on cells; however, the results of in vivo study results are inconsistent.^{49–51}

There is general agreement on dose guidelines for LLLT,³⁹ but an infinite number of combinations and permutations of parameters are possible.⁵² Rationale behind protocols remains unclear, although laboratory findings indicate effects are dose dependent.⁵³

Human Studies

Tissue healing and pain control are the main areas for which laser therapy is used in people.²⁹ Wound healing, soft tissue injuries, and pain apparently respond well.

Pain

LLLT may be used for management of pain.²⁹ Laser significantly reduced pain and improved movement in people with rheumatoid arthritis⁴² and osteoarthritis.⁵³

LLLT can directly induce analgesia when locally applied and indirectly when used at acupuncture and trigger points.³² People with cervical pain were managed with LLLT, and axonal beading by delayed nerve transmission was thought to occur.⁵²

Studies in horses are lacking, but 14 horses diagnosed with chronic back pain were treated with laser (904 nm) acupuncture in an uncontrolled clinical trial.⁵⁴ Back pain was eliminated in 10 horses, nine of which continued to perform at an acceptable standard 1 year later.

Musculoskeletal Use in People

Twelve musculoskeletal conditions (excluding osteoarthritis) were included in a meta-analysis, in which there was an equal number of positive and negative outcomes.⁵⁵

There was no evidence to support the use of LLLT for post-traumatic joint disorder, myofascial pain, and rheumatoid arthritis. A Cochrane review of the use of a 904-nm laser concluded that LLLT was effective for fast pain relief and quicker functional recovery, most specifically in the treatment of rheumatoid arthritis.⁵⁶ Using ultrasonographic assessment, there was a decrease in tendon diameter in people with de Quervain's tenosynovitis after 2 to 4 J/cm² LLLT (wavelength not specified).⁵⁷

Animal Studies

Of U.K. chartered physiotherapists surveyed in 1994, 64% used laser in the treatment of horses and dogs.⁵⁸ Laser therapy in animals is used for pain relief, wound healing, and to promote hoof growth.⁴³

There are mixed results in research studies of LLLT in animals.³¹ In an uncontrolled clinical trial in Standard-breds, there was a successful outcome after treatment of soft tissue injuries using a 904-nm laser.⁵⁹

Wounds

In experimental studies using LLLT, results are often inconclusive or mixed, with both positive⁵⁹ and negative outcomes.⁶⁰ Closure of chronic canine wounds was thought to be enhanced in a noncontrolled case report,⁶¹ but this article is typical of much of the LLLT literature—anecdotal evidence lacking the necessary scientific format for appropriate analysis. Sutured teat wounds in dairy cattle were irradiated by LLLT, and histopathological examination and laser Doppler flowmetry demonstrated improved healing.⁶² The effect of laser on equine wound healing was reported.⁶³ Surgically transected rat medial collateral ligaments exposed to laser (GaAlAs) gained a larger fibril diameter compared with controls.⁶⁴ Laser research is generally poor quality, with inadequate study design, lack of controls, and inconsistent recording of treatment parameters.³² However, enough evidence exists to justify continued investigation.⁶⁵

ELECTRICAL STIMULATION

Transcutaneous electrical nerve stimulation (TENS) is widely used to modify pain, whereas neuromuscular electrical stimulators (NMES) are used for muscle reeducation, prevention of muscle atrophy, and enhanced joint movement. Almost all electric stimulators are TENS units; they work transcutaneously through surface electrodes to excite nerves. TENS can stimulate muscle fiber activation in both normal and denervated muscle. NMES is used to treat a wide variety of physiological disorders and injuries in people and animals. It is the administration of an electrical current generated by a stimulator that travels through leads to electrodes placed on the skin to depolarize the motor nerve and produce a skeletal muscle contraction.

Electrical Current/Waveforms

Three types of current are commonly used:

1. Continuous direct current—unidirectional electrical current that flows for 1 second or longer
2. Continuous alternating current—changes direction of flow at least once every second (e.g., interferential)
3. Pulsed current (AC or DC)—unidirectional or bidirectional flow of charges (AC or DC) that periodically stops for a finite period. All NMES are pulsed current stimulators.

The phase duration is the time in which the current flows from the baseline in one direction and back to the baseline. The current may be monophasic, in which the pulse duration and the phase duration are the same, or biphasic, when the two phases make up one pulse. Pulsed current consisting of a bidirectional flow of charge is called biphasic pulsed current. When the duration of flow in each direction is the same, but the amplitude-dependent features differ, then the biphasic current is termed asymmetrical. Zero net DC current occurs when the total charge in one phase equals the total charge of the other phase. Both pulsed AC and DC current forms are commonly used in portable and clinical model NMES units.

Parameters Used in Neuromuscular Electrical Stimulation

Amplitude

Increasing the current intensity (milliamps) induces a stronger force of muscle contraction by recruitment of motor nerves at greater distances from the electrode. Lowering the skin's resistance decreases the driving voltage necessary for skin penetration, making stimulation more comfortable. Fortunately, horses have low skin resistance, and less current intensity is required to produce a sensory and motor effect.

Increased current amplitude is required to produce a given amount of muscular force if the pulse or phase durations are short. Symmetrical or asymmetrical biphasic pulsed currents use intermediate current amplitude levels.

Pulse Duration

Pulse duration of 200 to 400 μ s produces powerful contractions while minimizing the likelihood of recruiting many pain fibers. As the pulse duration increases, smaller-diameter pain fibers are recruited.

Pulse Rate

Pulse rate (frequency and pulse per second) is the number of pulses delivered per second and is measured in hertz (Hz). Tetanic muscle contractions may be produced with frequencies as low as 20 Hz. A maximum force contraction generally occurs between 60 and 100 Hz, and fatigue will occur as frequency increases.

Duty Cycle

Duty cycle is the ratio of on time to total cycle time, expressed as a percentage. On time is the period in which a series of pulses is delivered. Off time is the time between on times. As the on time increases, muscle fatigue increases. A horse with severe atrophy may require a longer off time to recover between contractions; therefore monitoring of fatigue is required.

Ramp

Ramp refers to a gradual change in current amplitude and results in a gradual and more comfortable change in force of muscle contractions.

Recruitment

NMES recruits type II (fast-twitch) fibers before type I (slow-twitch) fibers, the reverse of the muscle recruitment pattern seen in a volitional contraction.⁶⁶ Increasing the pulse duration increases the recruitment of smaller diameter

motor units at the same depth. Increasing the amplitude or pulse duration affects the strength of contractions because additional muscle fibers are recruited. Increasing the frequency results in the existing motor units firing at a faster rate and increases the strength of contractions, but it will also result in more fatigue.

Indications for NMES Treatment

NMES is commonly used for the treatment and rehabilitation of people who have had neurological or orthopedic injury. Examples include spinal cord injury, paralysis, or paresis from neurological disease and more commonly in joint disease or joint pain. NMES is used to mobilize and strengthen after edema, contractures, or surgical procedures resulting in nerve injury, to minimize atrophy, improve strength, halt the loss of volitional control, improve sensory awareness, decrease pain, and correct gait.

NMES was shown to halt muscle atrophy and improve recovery after reinnervation in rats with surgically severed peroneal nerves,^{67,68} although there may be detrimental effects, including altered muscle structure⁶⁹ and muscle-generating capacity.⁷⁰ NMES of the triceps brachialis muscle in monkeys enhanced oxidative capacity and increased fiber size.⁷¹ Capillary proliferation was seen in response to increased muscle blood flow, resulting in proliferation of endothelial cells. Microvascular perfusion is enhanced when applied at intensities that produce muscle contractions.⁷²

Overall Effects of NMES

Increased muscle strength, muscle mass, and oxidative capacity plus the ability to overcome the effects of reflex inhibition on muscles are possible effects.^{73,74} Care must be taken to avoid muscle fatigue, probably caused by the preferential recruitment of type II muscle fibers. If current intensity is too high, painful contractions may develop.

Transcutaneous Electrical Nerve Stimulation

TENS provides a degree of pain relief (symptomatic) by specifically exciting sensory nerves and thereby stimulating either the pain gate mechanism or the opioid system. These different physiological mechanisms dictate how TENS is applied.

TENS is noninvasive and has few side effects compared with drug therapy. The most common side effect is an allergic-type skin reaction seen in 2% to 3% of people and usually caused by the material of the electrodes, the conductive gel, or the tape used to hold electrodes in place. Most TENS applications are now made using self-adhesive, pregelled electrodes, which have several advantages, including reduced cross-infection risk, ease of application, lower allergy incidence rates, and lower overall costs.

Machine Parameters

The current intensity (strength) is in the range of 0 to 80 mA (up to 100 mA). Although small, this current is sufficient because the primary targets are the sensory nerves, and provided these nerves are depolarized, TENS can be effective. The machine delivers "pulses" of electrical energy, and pulse rate varies from about 1 or 2 pulses/sec (pps) up to 200 or 250 pps. In addition to the stimulation rate, the duration (or width) of each pulse may be varied from 40 to 250 μ s.

Most modern machines have a burst mode in which the pulses are allowed out in bursts or "trains," usually at

a rate of 2 to 3 bursts/sec. Modulation mode, which uses a method of making the pulse output less regular and therefore minimizing the accommodation effects, is sometimes available. Short-duration pulses can be effective because the sensory nerves have relatively low thresholds and depolarize following stimulation for less than a millisecond. The pulses delivered by the TENS stimulators vary between manufacturers but tend to be asymmetrical biphasic modified square wave pulses. Biphasic pulses have no net DC component, so skin reactions from a buildup of electrolytes under the electrodes are uncommon.

Mechanism of Action

Pain relief from TENS occurs by activating the pain gate mechanism and/or the endogenous opioid system. Pain relief from the pain gate mechanism involves excitation of the A β sensory fibers, and by doing so, reduces transmission of noxious stimuli from the "c" fibers through the spinal cord and hence onto the higher centers. Ideal pulse rate for A β fibers is high (90 to 140 Hz or pps), but it is unlikely a single frequency works well for every horse.

Alternatively, A δ fibers respond preferentially to much lower stimulation rates (2 to 5 Hz), and when stimulated activate an opioid mechanism that causes the release of endogenous opiates (enkephalins) in the spinal cord.

Both nerve types can be stimulated simultaneously by using burst mode stimulation. High-frequency stimulation (about 100 Hz) is interrupted (or burst) at the rate of about 2 to 3 bursts/sec.⁷⁵ Pulses at 100 Hz activate A β fibers and the pain gate mechanism, but burst excitation of A δ fibers activates the opioid mechanism with release of enkephalins.⁷⁵ For some horses, this is by far the most effective approach to pain relief.

Traditional TENS (Hi TENS, Normal TENS)

Traditional TENS uses stimulation at a relatively high frequency (90 to 130 Hz) and uses a relatively narrow pulse width (start at about 100 μ s). Thirty minutes is the minimal effective time, but it can be delivered for as long as needed. The main pain relief is achieved during the stimulation, with a limited "carryover" effect, that is, pain relief after the machine has been switched off.

Acupuncture TENS (Lo TENS, Acu-TENS)

Acupuncture TENS uses low-frequency stimulation (2 to 5 Hz) with wider (longer) pulses (200 to 250 μ s). The intensity used is usually greater than with traditional TENS, resulting in a definite strong sensation. Thirty minutes are needed to deliver a minimally effective dose. Opioid levels are slow to build up, and the onset of pain relief may be slower than with the traditional mode. Once sufficient opioid has been released, it keeps working after cessation of the stimulation. Many human patients find that the stimulation at this low frequency at intervals throughout the day is an effective strategy. The "carryover" effect may last for several hours.⁷⁵

Brief Intense TENS

Brief intense TENS achieves rapid pain relief, but the strength of the stimulation may be too intense and intolerable. The pulse frequency (90- to 130-Hz band) and the pulse width (200- μ s plus) are high. The current is delivered at, or close to, the tolerance level, and the energy delivered

is high compared with the other approaches. Fifteen to 30 minutes is all that can be tolerated.

Stimulation Intensity

In human medicine, the most effective intensity management appears to be related to what the patient feels during stimulation, and this may vary from session to session. In veterinary medicine, it is not possible to determine the sensory response in the same way. Horses show a visible endorphin response demonstrated by body posture and eye dilation. Resentment is clearly displayed by a high head carriage, tail swishing, and an obvious dislike to what is being done.

Electrode Placement

For maximal benefit, target the stimulus at the appropriate spinal cord level (appropriate to the pain) by placing the electrodes on either side of the lesion (painful area). Some alternatives that are effective, most of which are based on the appropriate nerve root level: stimulation of appropriate nerve root(s), the peripheral nerve, motor point(s), trigger point(s), or acupuncture point(s),⁷⁶ or appropriate dermatome, myotome, or sclerotome.⁷⁷

A two-channel application can be effective for treatment of vague, diffuse, or particularly extensive pain or the

management of a local and a referred pain combination (one channel used for each component).

Contraindications (from Human Medicine)

- Application of the electrodes over the trunk, abdomen, or pelvis during pregnancy
- Patients who have an allergic response to the electrodes, gel, or tape⁷⁹
- Dermatological conditions
- Patients with current or recent bleeding, hemorrhage, or with compromised circulation (e.g., ischemic tissue, thrombosis, and associated conditions)
- Application over the anterior aspect of the neck or carotid sinus

Precautions

- If there is abnormal skin sensation, the electrodes should preferably be positioned in a site other than this area to ensure effective stimulation
- Avoid active physes

TENS is a noninvasive method of giving pain relief; however, despite extensive studies in people,^{66,67,72,76-80} there are few studies analyzing the therapeutic effect in veterinary medicine.

Chapter 95

Osteopathic Treatment of the Axial Skeleton of the Horse

Chris Colles* and Julia Brooks

Osteopathy originated in the United States with a Kansas physician, Andrew Taylor Still. He envisaged a system of healing that placed emphasis on the structural integrity of the body as being vital to the well-being of the organism. As knowledge of physiology and anatomy advanced, a concept evolved of the nervous system as an information network constantly changing and adapting in response to sensory information from the body and the environment. This knowledge allows a move away from the idea of pathological dysfunction as the only cause of illness to a concept of physiological (or somatic) dysfunction.¹ To use a computer analogy, the body may suffer from software failure (physiological malfunction) and hardware failure (pathological malfunction). To extend the analogy, osteopathy may be thought of as a form of reprogramming.

Chiropractic treatment evolved at around the same time as osteopathy and is similar but subtly different. The

differences are largely philosophical; both forms of treatment rely on mobilization of joints. Chiropractors in equine practice tend to look primarily for positional changes associated with skeletal dysfunction. Treatment is directed principally at restoring joint mobility, with manipulation directed to the local site of dysfunction.

The osteopathic approach considers local tissue dysfunction as the direct result of trauma or the breakdown of compensatory mechanisms consequent to past trauma. The diagnostic approach is based on identifying patterns of dysfunction, with minimal reliance on positional factors and emphasis on the interactions of the entire spine. Treatment is aimed not only at restoring local function but also at identifying and removing factors that predispose to acute relapse. Therefore treatment frequently involves tissues distant to the perceived area of local dysfunction.

NEUROPHYSIOLOGICAL BASIS OF OSTEOPATHY

It is not uncommon in clinical practice to encounter horses that exhibit musculoskeletal signs for which no pathological cause can be established. The osteopathic philosophy accommodates these horses with the concept of somatic dysfunction. This concept is fundamental to osteopathy and describes a disturbance in the neurological networks that affects the function of the body (software failure). In other words, somewhere in the course of entering information from the environment and body, processing the information in the central nervous system, and then generating a motor response, something has gone wrong. Clinically this presents as a horse with signs such as stiffness, loss of performance, poor coordination, or gait abnormality for which no pathological process can be identified. Osteopathic treatment is directed at changing the signals to the

*In the previous edition, this chapter was coauthored by the late Mr. A.G. Pusey, DO, FeCert. I am very grateful to Miss J. Brooks, DO, MSc, wife of the late Mr. Pusey, for assistance in updating this chapter.

neural network to modify the way sensory information is processed and thus to correct the motor response generated in the central nervous system.

To explore this concept, it is necessary to appreciate aspects of neurological activity not only under normal circumstances and as part of the protective response to injury, but also when long-term and inappropriate changes occur that adversely affect function of the body.

Normal Neurophysiology

In a normal horse, sensory and motor systems work together to achieve optimum function.

Sensory Component

The peripheral sensory system has two categories of neurons that provide information to the central nervous system. The division is made based on fiber size. The fast, low-threshold large fibers carry the sensation of touch and proprioception, and the high-threshold small fiber system (C and A δ fibers) conveys potentially painful nociceptive and temperature modalities. In the spinal cord, these neurons synapse on interneurons where the first stage in information processing occurs. How the signals from the periphery are modified and sent onward to cortical areas for interpretation relies in part on the balance between large fiber input and small fiber nociceptor activity. This balance forms the basis of the pain gate theory where small fiber input, which may potentially be decoded as pain, can be held in check by large fiber activity. Under normal circumstances, much of the nociceptive input is screened out at the spinal cord level and never progresses to register as a painful sensation.

The sensory information will initiate and/or modify activity of the motor system.

Motor Component

The basic motor pattern is one of mutual inhibition of flexor and extensor neurons,² providing a balance between agonist and antagonist muscles. To refine the movements, proprioceptive information is sent constantly from muscle spindles and joint receptors back to the spinal cord. As sensory nerves enter the spinal cord, they send off sprays of ascending and descending collateral fibers, which synapse on interneurons that have connections within the spinal cord segment, with other spinal segments up and down the cord, and with tract cells up to the brainstem. The result is a network of neurons processing information from the body and environment. These generate flexible patterns of motor activity (sometimes referred to as *central pattern generators* [CPGs]). Thus a pattern of nerve activity is generated where the primary function is to move a limb, but simultaneously vital secondary functions are engendered—for example, changing the tone in the central musculature to counteract the changing load on the axial skeleton.

CPGs can cause many different routine patterns by virtue of the number and variety of interconnections, whose characteristics are determined by cellular and synaptic connections of the neurons. These patterns develop over time by a process of repetition and learning. Thus the inconsistent swing of a learner golfer becomes a confident, automatic swing after many hours of repetitive practice. This involves a process of chemical changes within a neuron

and new synaptic connections with other neurons, which speed up or “fast track” a particular response and result in a consistent and reproducible pattern of motor activity.

Autonomic Component

Alongside skeletal activity, autonomic changes such as alterations in blood flow are incorporated to provide the necessary humeral environment for motor activity.

Response to Injury

In response to injury, a number of events occur, which involve not only the sensory and motor pathways but also the autonomic system. A painful stimulus is conveyed from the periphery along small caliber nociceptors to the spinal cord. If the stimulus is of sufficient intensity, it will pass on to the brain to register pain. It will stimulate motor neurons in the ventral horn, resulting in paravertebral and peripheral muscle spasm,³ and stimulate sympathetic activity in the lateral horn, causing reduced blood flow to the skin.⁴ These neurophysiological changes represent a protective response against further injury and will, in the short term, affect the function of the body.

Once these defensive measures are activated, a control mechanism exists at the level of the spinal cord to modify this activity to prevent constant discomfort. Mediated by the large fiber system input of discriminatory touch and proprioception and by descending inhibitory cortical activity, the pain gate can be closed to painful stimuli. This can be demonstrated by rubbing an injured area to ease pain. It is the balance between large and small fiber stimulation and higher center input that determines the activity of the interneurons and therefore sensory, motor, and autonomic responses.

In the short term, these responses are protective. If they persist, however, changes occur in the activity of the neuronal network that results in altered pain states and impaired function.

Altered Neurophysiology

It is tempting to consider the reactions of the neurons to injury as hard wired, with a certain level of stimulus giving a corresponding magnitude of response. In fact, these neuronal networks are plastic, and the sensitivity of neurons to stimuli can be altered at any point in the pathway. In some circumstances, this process of sensitization or facilitation, as it is sometimes called, can be useful, for example, patterns of motor neuron firing during the acquisition of a new skill. However, when pain circuits are involved, a lower firing threshold may result in neurophysiological changes that affect function of the body long after the original injury has resolved. This is the basis of the somatic dysfunction concept that encompasses distortion in sensory, motor, and autonomic activity in the absence of any obvious pathology.

Sensory Effects

A lowered threshold for firing may occur at any point in the sensory system extending from peripheral receptors through to the spinal cord and brain. In response to injury, nociceptor nerve endings produce neurochemicals such as substance P.⁵ Combined with other inflammatory mediators such as prostaglandins and serotonin, the firing threshold is lowered, and the intensity at which the

nociceptors will fire is increased. This local sensitization is generally responsive to treatment with antiinflammatory medication.

If nociceptor activity is intense or prolonged, changes can occur in the chemistry and structure of the interneurons of the spinal cord.⁶ These can be traced 3 to 7 days after only 45 minutes of moderate nociceptive stimulation.⁷ These changes lower the threshold for interneuron firing in a process called *facilitation* or “wind-up.” They become supersensitive to afferent input and internal network activity within the spinal cord and will activate a pain circuit at an inappropriately low level of nociceptive input. This is the mechanism underlying hyperesthesia.

A further stage in this central sensitization of interneuron pools is the development of allodynia, where even an innocuous stimulus such as a light touch results in a pain response. The clinical manifestation may be a “cold-backed” horse or one with sensitivity around the poll. Furthermore, the central pain pathways may be driven without any peripheral input at all. In experiments when afferent activity was blocked by sectioning the dorsal (sensory) root, a sensation of pain accompanied by autonomic and motor responses may still be present, driven by the output of the sensitized interneurons. This means that pain persists long after the original injury has resolved. Even when pain is no longer felt, the neuronal pool remains sensitive, and relatively low levels of nociceptive activity will produce a pain response inappropriate to the magnitude of the stimulus. This may account for horses with recurrent injuries that occur with minimal physical provocation.

Another characteristic of central sensitization is the development of antidromic activity in the sensory nerves. Although under normal circumstances a sensory neuron is stimulated at the periphery and transmits a signal back toward the spinal cord, it is in fact capable of firing from the center outward to the receptor, in what is termed the dorsal root reflex.⁸ On reaching the periphery, depolarization of the nerve endings has the same effect as depolarization as a result of a noxious stimulus from an injury. Proinflammatory neurochemicals are released from the nerve into the surrounding area and trigger an inflammatory cascade. This centrally driven inflammatory response may explain those cases of intermittent limb swellings and dysfunction for which no pathological cause can be identified.⁶

Alongside the deleterious effects of persistent sensory changes, there are motor and autonomic effects that will affect neuromusculoskeletal function.

Motor Effects

Part of the response to injury is contraction of muscle, which protects the area from further harm. In the short term, this is a helpful emergency measure. However, persistent muscular changes are not desirable. There are a number of biomechanical, neurophysiological, and biochemical consequences arising from a muscle that remains in a contracted state.

From a biomechanical perspective, muscle spasm causes asymmetry of and restriction in joint movement. This not only has a local effect but also causes adaptation of movement by other parts to accommodate this loss of function. These distant sites may themselves become symptomatic in the long term.

On a neurophysiological level, persistent contraction reduces joint movement and results in length changes in muscle fibers. This diminishes the amount of large fiber input from muscle spindles and joint receptors into central interneuron pools and shifts the balance in favor of small fiber nociceptor activity and stimulation of pain circuits.

The other consequence of reducing information from proprioceptors is that it impairs the ability of the central processing centers to map the position of the body in space. This is of particular importance in the cranial cervical spine, where the greatest concentration of proprioceptors is found⁹ and which is a vulnerable area when a horse falls. Joint stiffness and muscle contraction in this area following an injury will alter feedback from this level. This affects the ability of motor pattern generators throughout the spinal cord to modify activity in response to alterations in body position and may produce changes ranging from subtle gait disorders to ataxia. Clinically there may be no obvious signs, but it will affect the horse's potential and leave it more susceptible to acute injury.

Biochemical effects of muscle spasm influence factors that regulate the number of sarcomeres, which are the building blocks of muscle mass. Although stimulation of muscle by motor neurons is an important ingredient in muscle development, another clinically significant factor is stretch of the muscle fibers.¹⁰ Stretch results in the production of a substance referred to as mechano-growth factor, which stimulates development of muscle mass. Lack of movement through an area may be responsible for the loss of topline and underdeveloped quarters often seen in a stiff horse.

Autonomic Effects

Alongside the sensory and motor effects that are characteristic in somatic dysfunction, altered autonomic patterns are also generated.

Thermography can be useful to detect this aspect of somatic dysfunction. In a “normal” horse, a reproducible thermographic pattern is observed, reflecting cutaneous blood flow.¹¹ Where facilitated segments exist, sympathetic activity in the lateral horn reduces surface blood flow, giving distinctive segmental cooling. In addition to local segmental changes, the pattern may be disrupted throughout the length of the spine, giving a visual record of changes in autonomic nerve output.¹⁰

Clinical Implications for Altered Neurophysiology

These mechanisms may explain some of the nonspecific lameness and back pain that tend to be recurrent. A diagnosis based on pathological condition of tissue (demonstrated by radiographic and scintigraphic examinations or by diagnostic analgesia) is not possible because the abnormality results from physiological changes in the motor, sensory, and autonomic patterns generated by the facilitated neuronal segment. Gait disturbance may be observed, and muscle spasm, joint stiffness, and tissue texture changes may be appreciated by palpation and passive motion testing.

EFFECTS OF OSTEOPATHIC TREATMENT

The concept of somatic dysfunction means that if an injury is treated exclusively at the periphery but central

sensitization has occurred, then treatment may be ineffective or the benefits may be short lived.

On a neurophysiological level, osteopathy seeks to reduce this central sensitization of the facilitated segment by increasing large fiber signaling into the central nervous system. This shifts the balance of input away from small fiber nociceptive traffic, thereby closing the pain gate and inhibiting pain circuits. This has the effect not only of reducing discomfort but also of increasing movement, improving proprioception, encouraging muscle development, and promoting nutrition to the musculoskeletal system.

In practical terms, most techniques are directed toward restoring movement to stiff joints to optimize maintenance of postural position and functioning of the body. Local musculature is relaxed and mobility improved, which is associated with an increase of mechanoreceptor activity carried by the large fiber system into the interneuron pool. The treatment may take a number of forms, including soft tissue techniques, articular techniques, and mobilization and functional techniques.

Soft tissue and articular techniques stretch the skin, fascia, and muscles to improve pliability of and nutrition to the periarticular tissues and also to allow the joints to move in a full range. These techniques include massage and repetitive flexion and extension of restricted joints.

Mobilization techniques involve taking a joint with poor mobility to the point of maximum resistance (the restrictive barrier) and pushing through this barrier with a short-amplitude, high-velocity thrust. This causes relaxation of the muscles and improved mobility resulting from a sudden increase in large fiber input from mechanoreceptor activity, which resets the balance of inputs into the spinal cord and reduces central sensitization.

A successful approach in horses with long-standing, complex injuries is the use of functional techniques. This uses the concepts of ease and bind. A normal joint reaches a point (usually at the middle of its range of movement) where tension on the capsular ligaments and the overlying muscles is minimal. This is the point of ease, where a joint tends to rest naturally. Any movement away from the point increases tension or bind. This information is used by the central nervous system to monitor joint position and to generate an appropriate pattern of motor activity. Where the normal relationships between the joint structures have been disturbed, this point of ease is offset, and afferent information from that joint is changed. New reference points become imposed on the established networks, and the joint is less able to perform appropriately or to coordinate movement with other joints.

This new abnormal point of ease may be detected clinically by testing each range of movement (flexion/extension, side bending, rotation, translocation, and traction/compression). With the joint held in the position of ease, tension is minimal, and therefore afferent input into the spinal cord is minimal. This appears to reduce conflicting information entering the network and allows the old pattern to reassert itself. The old pattern is preferred by the system because over time neuronal connections have been created that fire more readily to generate this original learned response. This form of treatment relies on the osteopath establishing and maintaining one or, more commonly, several joints at the point of ease until the original

central pattern generators can reassert influence over the newly acquired patterns. This is a learned skill on the part of the osteopath and requires considerable tactile sensitivity and skill to adjust the tissues as the neurological patterns are modified. Among injured horses is a clinically challenging subgroup of 4- to 6-year-old horses that develop clinical signs as work becomes more demanding, rather than as a response to direct trauma. In these horses, it is tempting to conjecture that some form of perinatal injury may have occurred that has prevented the normal patterns from developing. These horses frequently undergo more treatment and require more careful rehabilitation than other horses.

Details of osteopathic techniques are beyond the scope of this chapter, but the reader is referred to an excellent textbook.¹¹

DIAGNOSIS AND CASE SELECTION FOR OSTEOPATHIC TREATMENT

Diagnosis should involve selection of horses with a somatic dysfunction and exclusion of horses with a pathological condition. Initially a conventional veterinary lameness examination should be performed. If the examination indicates a change in quality of movement rather than lameness, or if lameness is centered in the axial skeleton and no pathological process can be demonstrated readily (e.g., by radiological or scintigraphic evaluation), then the likelihood of a somatic dysfunction as the cause of lameness should be considered. Somatic dysfunction alters the way a horse moves and so may contribute to pathological change (e.g., synovitis in an overloaded joint). Once a primary pathological condition has been excluded, the process of making an osteopathic diagnosis can proceed. This diagnosis is based on somatic dysfunction, that is, how the component parts of the horse work together as a whole and how different areas of dysfunction or stiffness may contribute toward the problem.

An accurate case history is essential and should include the type of work the horse is expected to do and the level it is expected to attain. The history also highlights past injuries and illnesses and may reveal idiosyncrasies in behavior or movement that, although noticed by the owner, have not interfered with performance sufficiently to be a cause for concern. When considering the history, these subtle disturbances in motor function may, in retrospect, have been early signs of the coming crisis.

Examination begins by assessing muscle development and distribution of weight through all limbs in the standing horse. The horse should stand naturally with all cannon bones vertical and not shift weight constantly between limbs. Muscle development should be symmetrical, and the areas of muscle should be consistently developed throughout the horse. Areas of poor development over the top of the back, neck, or quarters should be noted. Similarly, uneven development or hypertrophy may be substantial. In particular, hypertrophy of the pectoral muscles may indicate that forward propulsion of the horse depends unduly on the forelimbs because of poor hindlimb function. Hypertrophy of the muscle over the atlas and axis frequently accompanies restricted joint movement at this level. Foot placement, shape, and shoe wear are also important for locating areas of dysfunction. When assessing feet,

however, it is necessary to differentiate between change caused by altered limb movement and problems caused by poor farriery.

Movement at a walk is more revealing than at the trot, when the horse tends to fix the neck and back to guard against pain. Observation gives an impression of how the horse moves as a whole and indicates which areas are functioning poorly. Balance and fluidity of movement from head to tail are as important as stride length, foot placement, and frank lameness. How the horse copes with long and short turns indicates problems with lateral flexibility. In particular, when the horse is turned short, the head and neck should flex evenly in the direction of the turn, and the hindlimbs should be crossed as the quarters move around. All limbs should be moved with easy flowing strides, showing consistent stride length and straight limb flight. The feet should be placed easily, and in particular the hind feet should not dig into the ground when placed. Limb movement that appears heavy, stiff, inconsistent, or mechanical should alert the observer to potential problems. Excessive head and neck movement in time with the limbs is also abnormal. Substantial lateral movement of the pelvis, often associated with patches of worn hair under the back of the saddle, indicates reduced movement in the lumbosacral spine. The pelvis and tail being carried to one side also indicates uneven tone in the spinal musculature. Uneven height between the tubera coxae also should alert the clinician to potential problems.

The transition from walk to trot can be revealing, and any tendency to raise the head or skip in the transition indicates problems, probably in the region of the cervicothoracic junction. Assessing individual joint movements is useful, but it requires considerable skill and powers of observation. Running the hands down the paravertebral muscles from the occiput to the tail may reveal areas of muscle hypertrophy or spasm, and most importantly tissue texture can be felt. Moving the joints through the relevant ranges of motion identifies those that are stiff.

Diagnosis requires consideration of past injuries, the way the horse moves overall, and identification of dysfunction in specific areas. Initially, the clinician may only be able to form a working hypothesis, which will be refined once treatment begins. Where problems have been present for some time, the horse will have developed altered patterns of posture and movement to work around poorly functioning areas. These alterations may occur at several levels because of the interconnections of the neural networks. Ascertaining what is the site of the primary injury and what are secondary changes may be difficult.

INFRARED THERMOGRAPHIC IMAGING

Thermographic examination in the horse has proved to be an invaluable tool to confirm somatic dysfunction.¹² It is important to realize that areas of cooling are more important in diagnosing sympathetic dystonia than are increased temperatures. Thermography is prone to artifactual results, and interpretation can be reliable only if image acquisition is carried out in a temperature-controlled environment (between 18 and 22° C) using an absolutely consistent technique.

The horse must be clean and dry because moisture absorbs infrared radiation and causes false readings. Hair

length should be consistent because hair has an insulating effect, and horses that have clipped coats or rubs from rugs present difficulties in interpretation. Different coat colors may be of different hair length or density, which causes artifacts. When moulting, areas of different colored hair may moult at different times, again giving rise to artifactual results. Before performing a thermographic examination, horses should be acclimatized to the room temperature for as long as it takes for the surface temperature to remain stable. The time required depends on the difference in ambient temperature of the environments inside and outside the thermography room. The room should be free of drafts and direct sunlight.

In a normal horse, a reproducible thermographic pattern is observed, reflecting cutaneous blood flow.¹³ Where facilitated segments exist, sympathetic activity in the lateral horn reduces surface blood flow, giving distinctive segmental cooling. In addition to local changes, the pattern may be disrupted throughout the length of the spine, giving a visual record of changes in autonomic nerve output. Certain specific injuries give areas of increased blood flow and an increase in surface temperature. These injuries are usually around the head or in the lower limbs, where little or no overlying muscle is present.

In a normal horse, the surface temperature should be within 1.5° C over the neck and body of the horse and in the limbs proximal to the carpus and tarsus. The head and lower limbs are generally cooler. A useful guide when setting the thermographic factors is to assume the eye will be the hottest normal area and to set up the camera with this as the maximum temperature. Changes of 5 to 6° C are severe, so a temperature range of about 6° C is ideal. If the horse has parts of the coat clipped, then changes in the level of the window may be required to accommodate the clipped areas of the body. Particularly important is a dorsal view of the back, where a relatively warm dorsal midline stripe is seen, with the muscle on either side symmetrical and between 0.5 and 1° C cooler. When interpreting thermographs of the neck and back, changes of less than 1° C from the normal may be discounted. Changes in excess of 1° C usually indicate sympathetic dystonia, the importance of which must be interpreted in the light of information regarding clinical signs seen and the use to which the horse is put. It is likely that horses frequently suffer low-grade back pain or stiffness, which may not be of particular clinical significance if they live relatively sedentary or gymnastically undemanding existences (e.g., a racehorse or hunter performs satisfactorily with minor changes in the cranial aspect of the neck or thoracolumbar spine, which would cause unacceptable stiffness or gait modification in an event or dressage horse).

Figure 95-1, A to C (Color Plate 5), shows the thermographic appearance of a completely normal horse. One should bear in mind that few horses meet this degree of perfection, but they may still perform adequately at the required use. The most common area of the spine to show joint stiffness is the cranial aspect of the neck, with changes to the occipitoatlantal and atlantoaxial joints. This group of injuries results in a cold band running obliquely ventrally in the neck from about the level of the occiput (Figure 95-2; Color Plate 6). This band becomes narrower with time, and although a substantial temperature change is visible in the acute stage, over an initial period (probably

Fig. 95-1 • Thermographs show the appearance of normal horses. The color scale represents 5.6°C using 10 colors; that is, each color represents about a 0.5°C change in temperature. The color bar under the image shows the colors used; those to the right side are the hottest, and those to the left are the coldest. White is above the top of the scale, and black is below the scale. **A**, Lateral image of the head, neck, and shoulder. **B**, Lateral image of the thorax, abdomen, and hindquarters. **C**, Oblique dorsal image from behind the horse looking toward its head and neck. Temperature variation is 1°C over the neck, trunk, and hindquarters. A warm midline dorsal stripe along the back extends from the withers to the base of the tail, with symmetrical muscle temperature on either side.

Fig. 95-2 • Lateral image of the neck of horse with reduced mobility in the occipitoatlantal and atlantoaxial joints. A cool line runs obliquely from the region of the atlantoaxial joint caudally to the base of the neck and is 1.5°C cooler than the surrounding muscle, indicating an area of sympathetic dystonia.

Fig. 95-3 • Lateral image of the neck of horse with reduced mobility in the neck. There is clinically significant cooling from the occiput caudally to the level of the sixth and seventh cervical vertebrae, indicating a problem involving all joints in the neck.

about 2 years), the temperature change becomes less noticeable. Stiffness or injury farther caudal in the neck is accompanied by cooling of the surface temperature overlying the affected area (Figure 95-3; Color Plate 7). Because the nerve supply to the muscles of the shoulder arises from the caudal

aspect of the neck, injuries to the spine between the shoulders are difficult to see thermographically, but a cold band running vertically down the back of the shoulder region (Figure 95-4, A; Color Plate 8, A), usually accompanied by cooling of the entire thoracic area and hindquarters, is an

Fig. 95-4 • Lateral images of the thoracolumbar area of two horses, both showing substantial cooling in the musculature of the dorsal spine from the saddle region caudally. **A**, The vertical cranial boundary to the zone of cooling indicates that the injured area is in the region of the cervicothoracic junction, but the shoulder muscles overlying this area receive innervation from the lower neck, partly masking the muscles supplied by the upper thoracic area. **B**, The typical appearance of cooling in the muscle resulting from an injury to the region of the twelfth thoracic vertebra, with the cranial border of the region running obliquely ventrally and caudally. This horse has been clipped, but long hair left on the hindlimb produces an area 5° C cooler than the surface temperature of the thorax of the horse.

indicator of injury to the cervicothoracic area. Cooling of the hindquarters arising caudal to a diagonal band from the level of about the twelfth thoracic vertebra generally indicates injury at this level of the thoracic spine (Figure 95-4, B; Color Plate 8, B). Two other changes are of particular clinical significance. Any break in the normal dorsal stripe running along the midline of the back or substantial cooling on either side of this stripe indicates a change in sympathetic activity in that region (Figure 95-5; Color Plate 9). Second, cooling of the distal aspect of a limb may be clinically significant. If the ambient temperature decreases below about 15° C, normal physiological changes reduce blood flow in the distal aspect of the limbs to conserve body temperature. This causes cooling of the distal aspect of the limbs (distal to the carpus or tarsus, unilaterally or bilaterally), but such limbs should still show a surface temperature 5 to 6° C cooler than the trunk temperature. If severe injury has occurred at the base of the neck or in the lumbar region, then the temperature of the distal aspect of the limb may decrease to equal the ambient temperature.

Fig. 95-5 • Dorsal image of horse showing abnormal temperature patterns of the thoracolumbar spine. Note the complete loss of the normal central stripe, with substantial cooling indicating the presence of reduced mobility of the entire thoracolumbar spine and pelvis. The asymmetrical nature of the temperature pattern indicates the horse is likely to move with an asymmetrical gait, resulting from increased muscle tone on the left side of the body.

More detailed analysis of the thermographic changes seen is beyond the scope of this chapter.

TREATMENT

Because of the vast number of interneural connections and the ramification of effects on the spinal cord, the entire spine must be considered as one interrelated structure, and treatment may have to be provided at several levels. Sedating the horse is useful because treatment requires identification of specific areas of stiffness or reduced movement. If the horse is sedated adequately, then the absence of conscious movement allows the osteopath to feel underlying deficiencies more easily. Sedation is particularly helpful when using functional techniques that monitor subtle changes in joint position. Osteopaths in the United Kingdom undergo a 4-year university course that includes considerable theory and practical training. The techniques used require considerable practical experience to be successful; therefore this chapter can only begin to outline treatment.

After the osteopath performs the static and moving examinations described earlier, he or she starts a physical examination, feeling the tone and physical character of the muscles and the extent of movement of the joints, usually starting at the head and working along the neck and back to the tail. It is necessary to try to determine which joints show restricted movement, which areas show abnormalities caused by primary injury, and which changes are secondary to the primary affected areas. Experience allows the osteopath to determine which area must be treated first. The areas showing somatic dysfunction tend to be interrelated and must be treated in a specific order if treatment is to be successful. Starting treatment on an area showing restricted movement secondary to another abnormal area is doomed to failure. However, treatment of a key area often results in dramatic relaxation throughout the spine. The basic techniques of treatment have already been outlined and rely on stimulating the activity of the large caliber fibers, thereby inhibiting the interneuron pool and blocking the small fiber (pain) signals. The results are

effective in most horses, and once the neural activity returns to normal, the horse tends to maintain this state.

In a small number of horses the problem may be so ingrained and widespread that general anesthesia may be needed to facilitate assessment and treatment. The plane of anesthesia is light, and the horses are in good health; thus the risks of the procedure are minimal. Assessment of individual joint complexes can be made throughout the spine with the horse under general anesthesia. It is remarkable how often gross dysfunction of these complexes can be detected with the horse anesthetized, when they had previously been effectively concealed by the capacity of the body to set up compensatory mechanisms. Treatment is still based on the principles outlined above, but the horse is positioned on its back, allowing movements such as rotation of the thoracolumbar spine, which cannot be achieved in a standing horse. Using all limbs simultaneously is also possible, allowing functional techniques (outlined previously) to produce a massive large fiber input to the interneuron pool. This is done by moving each limb to its position of ease, and then holding the position until relaxation is felt. By moving the limbs to maintain the positions of ease, the sympathetic dystonia can be unwound gradually. This technique, used with the horse under general anesthesia, allows a potent but gentle treatment to be carried out. In a standing, conscious horse, techniques are necessarily limited and are most effective with relatively short-term injuries.

RESULTS OF TREATMENT

Pusey et al¹⁴ reported on a trial carried out over 4 years, treating horses with chronic dysfunction using osteopathic techniques. Eighty percent of treated horses returned to the previous use, performing at the same or a better level than before treatment, at least 12 months after the last treatment. As might be expected, the authors concluded that results were substantially better among the later horses because of increasing experience of treatment techniques.

Another study was made of horses that had been treated under general anesthesia, having failed to respond satisfactorily to treatment under sedation. Follow-up information was obtained at least 1 year after the treatment was finished. Thirty-five horses were treated. Twenty-four (71%) of these had maintained improvement and returned to the previous level of work: 11 at the previous level and 13 at a higher level than previously. Eight (24%) horses did not respond to treatment, and two horses deteriorated. One horse was not available for follow-up evaluation. The authors concluded that given that these horses had long-term intractable problems, this was a justifiable and useful treatment technique.

We hope this brief overview shows the potential for osteopathy in a complementary role, alongside veterinary science, in treating neuromusculoskeletal problems in the horse.

Chapter 96

Shock Wave Therapy

Scott R. McClure

HISTORICAL PERSPECTIVE

Early studies in people in which shock waves (SWs) were used to disintegrate ureteral stones resulted in radiologically evident remodeling of the pelvis.¹ These findings sparked the initial studies investigating the use of SWs in orthopedic applications. These studies and anecdotal clinical use resulted in the initial five standard indications used in human medicine: (1) calcifying tendonitis of the shoulder (tendinosis calcarea), (2) tennis elbow (lateral epicondylitis), (3) golfer's elbow (medial epicondylitis), (4) heel spurs (plantar fasciitis), and (5) pseudarthrosis. Focused shock wave therapy in horses started in Germany in 1996, and applications were primarily based on those from human medicine.² Because of positive experiences treating people with insertional desmopathies, the first equine application was the use of shock wave therapy (SWT) in horses with proximal suspensory desmitis. Initial clinical responses were positive; therefore SWT was attempted in numerous other equine conditions, including navicular syndrome and distal hock joint pain.^{3,4} Initially, the probe

was positioned behind the navicular bone from the heel, but when ultrasonographic imaging showed that the distal sesamoidean impar ligament could be seen through the frog, this location was then used to administer SWT to the navicular bone and associated structures.

The first equipment was large, requiring water cycling and degassing, and use was limited to horses under general anesthesia. The development of more affordable, portable, and durable equipment led to an initial expansion of its use and applications. However, as further knowledge was gained in equine medicine and surgery, the use of SWT has contracted somewhat, and attention is now paid to applications that consistently provide good clinical outcomes.

SHOCK WAVE GENERATORS

Two distinctly different pressure waves have been loosely described as SWT, SWs and radial pressure waves (RPWs). True SWs are pressure waves that meet specific physical parameters, including a rapid rise time (within nanoseconds), high peak pressures, and a gradual decrease in pressure over a few milliseconds, often with a negative pressure component (Figure 96-1 and Table 96-1).⁵ SWs occur naturally associated with lightning, planes breaking the sound barrier, or explosions. Electricity is used as a driving energy source to generate SWs used for medical purposes. RPWs are generated by pneumatically powered sources that drive a metal rod to strike a plate in contact with the skin surface. RPWs have slower rise times and lower peak pressures than

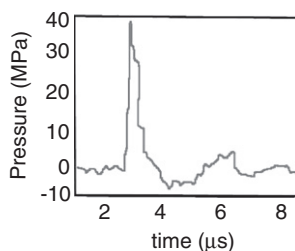

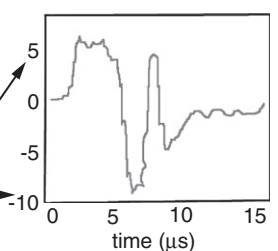

Fig. 96-1 • The schematic demonstrates the three types of pressure waves described. Focused shock waves concentrate the pressure at a focal point that can be centered up to approximately 75 mm deep. Planar shock waves are not focused and have a more diffuse pattern with less penetration. Radial pressure wave generators have a lower maximum pressure and deposit the maximum pressure on the surface. *Includes "focused" end piece.

SWs. Differences between SWs and RPWs are important because they may not affect tissue similarly; consequently, the type and equipment used are critical when evaluating the effect on tissues and efficacy of treatment. Editors' note: However, published results in the horse have to date

shown little difference in efficacy. A comprehensive review of SWs and RPWs, along with a description of equipment currently available, was recently published.⁶

DOSE DEPENDENCE

There is a dose effect of SWT that is a combination of the energy flux density (EFD) and the number of pulses. The EFD (mJ/mm²) is the amount of energy (millijoules) in the focal area (mm²). There is a lower limit of EFD that must be reached for SWT to be effective and an upper level over which EFD is high enough to create damage at any number of pulses. This range depends on species, tissue being treated, waveform, and generator.

It is difficult to transpose doses from other species to horses. When 1000 pulses at an EFD of 0.28 mJ/mm² was applied to rabbit Achilles tendons, there was a useful inflammatory reaction; but there was inflammation and tendon necrosis at 0.6 mJ/mm².⁷ However, EFDs of 0.6 mJ/mm² or more are used in horses without complications. The minimal dose to achieve the desired effect is not known, and we may not need to use such high levels. There is a current trend to use low EFDs for a number of applications. One thousand pulses at 0.18 mJ/mm² stimulated neovascularization of the tendon-bone junction in dogs.⁸ A dose of 200 pulses at 0.12 mJ/mm² was better than 500 pulses in an Achilles tendonitis model in rats.⁹ At this time, the ideal energy levels and pulse numbers remain empirical in most equine applications.

The frequency (pulses/sec) of the pulse application appears unimportant, although SWT using lower frequencies takes longer. From a biological standpoint, frequency of all equine SWT applications is relatively slow, and tissue heating or other untoward biological effects seen at high rates do not occur, although white hair occasionally develops at treatment sites.

APPLICATIONS

Bone

Early studies of SWs on bones yielded variable results and were confusing. Very-high-energy treatment of rodent and rabbit bones resulted in physical disruption of the bone and periosteum, which led to the thought that bone remodeling in response to SWT was the result of physical damage.^{10,11} In other studies using more appropriate tissue and in different species, bone remodeling occurred without physical disruption. The ability for SWT to stimulate bone healing resulted in an interest to use SWs for the management of nonunion fractures. In one study, nonunion fractures were created in 10 dogs using segmental radial osteotomies.¹² Five dogs were treated with 4000 SWs at 0.54 mJ/mm², and five served as untreated controls. All treated dogs had osseous union by 12 weeks compared with only one untreated control dog.¹² The first widespread musculoskeletal use of SWs in people was for management of nonunion fractures. Clinical trials have consistently demonstrated bone healing following SWT in delayed union fractures and nonunion fractures. Wang reported 80% success¹³; Schaden, 75% success¹⁴; and Rompe, 72% success—results that were remarkably consistent.¹⁵

The mechanisms of SW-induced osteogenic stimulation are currently being investigated. There were increased

osteoprogenitor colony-forming units from the marrow of rat femora 24 hours after treatment with 500 SWs at 0.16 mJ/mm^2 .¹⁶ A dose response was seen with the highest supernatant concentrations of transforming growth factor- $\beta 1$ (TGF- $\beta 1$) after 500 SWs; lower numbers of pulses were ineffective, and higher numbers were inhibitory. The same treatment protocol (500 SWs at 0.16 mJ/mm^2) was administered to rats with segmental bone defects and resulted in increased expression of TGF- $\beta 1$ and vascular endothelial growth factor-A (VEGF-A) mRNA and increased osteoprogenitor cells.¹⁷ In both studies, it appeared that SWT stimulated osteogenesis without physical disruption of the bone. Subsequent studies have shown that SWT increases concentrations of VEGF and bone morphogenic protein-2, as well as neovascularization and ultimately an increase in load to failure in a rabbit femoral fracture model.¹⁸

The application of SWT to bone was the initial musculoskeletal application in people and horses. The applications and outcomes in human medicine have grown and are positive. The applications of SWs in horses have not been pursued as aggressively as may have been expected. One initial concern was the potential for the creation of microfractures that could weaken the bone after treatment, a theory that has some support. The application of 9000 pulses of RPWs at 0.175 mJ/mm^2 or 9000 SWs at 0.15 mJ/mm^2 to cadaver third metacarpal bones (McIII) from racehorses that suffered catastrophic injuries of the contralateral limb caused a small but significant increase in microcrack density, and RPWs increased microcrack length.¹⁶ In dorsal cortical bone specimens of the McIII 2000 pulses of SWs or RPWs subjected to pulse increments of either 500-SWs (0.15 mJ/mm^2) or RPWs (0.16 mJ/mm^2), there were no detectable changes in modulus of elasticity.¹⁷ Histologically, there were no increases in microfractures demonstrated with either SWs or RPWs.¹⁷ Microfractures did not develop in an *in vivo* study in which 1000 pulses at a high EFD (1.8 mJ/mm^2) were used.

In an *in vivo* equine pilot study that used 2000 SWs at 0.89 mJ/mm^2 , two treated McIIIs had 30% more activated osteons than the contralateral untreated control McIII.¹⁸ SWs were compared with periosteal irritation (stimulated by scarifying the periosteum with a needle) in the third metatarsal bone (MtIII) of four horses. The SW-treated MtIIIs had 56% more double-labeled osteons than those with only periosteal irritation, and the osteonal response was located at both the endosteal and the periosteal surfaces. This preliminary finding demonstrated that SWs exert an effect on bone that is different from simple periosteal scarification. Scintigraphic and histological examination of the fourth metatarsal bone after 2000 pulses at 0.15 mJ/mm^2 showed increased radiopharmaceutical uptake in the treatment area and an increased number of osteoblasts.¹⁹

Twenty-two Thoroughbred (TB) racehorses with dorsal metacarpal disease (see Chapter 102) manifest as pain on palpation, a thickened dorsal cortex of the McIII, and longitudinal radiolucent lines that were unresponsive to conventional therapy were treated with RPWs.²⁰ Three treatments at 2-week intervals were administered, and a modified training program was instituted. The mean time to the first race was 4.5 months. Similar results are seen with focused SWT. I treat horses with periostitis with focused SWT (0.14 mJ/mm^2 , 800 pulses), give 1 week of

walking, and then resume training for 2 weeks; the cycle is repeated two more times. When horses are treated early in the disease process, most can continue in training without an extended rest period.

Horses with stress fractures of the tibia, humerus, and the McIII are candidates for management with SWT. Without controlled studies, it is difficult to compare SWT with healing in horses with nontreated fractures or in those receiving osteostixis. It is my impression that TB racehorses with dorsal cortical fractures of the McIII can return to training in a similar period as those that have received osteostixis. Six of 10 horses with McIII stress fractures were pain free and/or showed radiological evidence of healing by 90 days.²¹ Two horses took more than 120 days, and two were retired for other reasons. In 20 horses with single oblique dorsal cortical McIII stress fractures treated with RPWs, the mean time from the last treatment to the first race was 5 months.²⁰

Horses with fractures of the second and fourth metacarpal (metatarsal) bones and exostoses are frequently treated with SWT. Focused SWT was used in four horses with closed fractures and in three with open, infected, comminuted fractures of the proximal aspect of the splint bones.²² Horses with infected fractures were first treated locally and systemically with antibiotics, local wound curettage, and ostectomy of small loose fragments. SWT began when signs of infection were resolved and the skin was healed. The horses were treated with three treatments at 10- to 14-day intervals. They were administered 600 to 900 pulses, depending on the size of the lesion, at an EFD of 0.15 mJ/mm^2 . Radiographs were obtained after the third treatment and 4 weeks later. Handwalking began after the second or third treatment. In horses without an infection, training began 10 to 12 weeks after fracture, whereas in those with infected fractures, training began 13 to 16 weeks after fracture. All the horses were sound and returned to normal use. There were no horses that did not undergo SWT for comparison.

Horses with fractures of the distal phalanx that can be approached with SWT through the frog are good candidates for treatment, but efficacy is anecdotal. Because it is not possible to get the SWs to penetrate through the hoof wall or the sole, fractures must be near the center of the distal phalanx and accessible through the frog. Some horses have shown positive outcomes.

There are only limited reports of using SWT in horses with long bone fractures and arthrodesis stabilized with internal fixation. Expense is a consideration, but access to apply SWT is a major limiting factor. SWT cannot be used effectively on horses with external coaptation such as a cast. SWT improved callus formation in the immediate postoperative period in dogs with bilateral 3-mm osteotomy gaps in the midtibia stabilized with a plate and treated with 2000 pulses at 0.18 mJ/mm^2 .²³ At 12 weeks there was more radiologically visible callus and more histologically evident cortical bone formation than in control untreated dogs.²³ Early treatment of fractures may be beneficial in the horse.

Tendons and Ligaments

In vivo studies of tendon and ligament injuries have provided support for the use of SWT. Rabbits with collagenase-induced patellar tendonopathy were treated twice with

1500 pulses at 0.29 mJ/mm^2 .²⁴ Tendons were harvested 4 and 16 weeks after SWT. SW-treated tendons had a 7% and 10% increase in strength at 4 and 16 weeks, respectively, compared with untreated controls. There were increased hydroxyproline concentrations in treated tendons and more blastlike tenocytes after 4 weeks. When 500 SWs at 0.12 mJ/mm^2 were applied to long digital tendon grafts placed to stabilize surgically disrupted anterior cruciate ligaments in rabbits, the treated bone-tendon interface had more trabecular bone ingrowth than controls.²⁵ The contact between the bone and tendon was improved, and subsequently the strength of the graft was increased 24 weeks postoperatively. Growth factors known to affect tendon repair, including TGF- β 1 and insulin-like growth factor I, were increased after SWT in rats.⁹

Tissue explants were used to evaluate the effect of SWs on healthy pony tendons and ligaments.²⁶ Six hundred pulses at 0.14 mJ/mm^2 increased glycosaminoglycan (GAG) and protein synthesis in explants harvested 3 hours after treatment. However, by 6 weeks there was a decrease in GAG and collagen synthesis.²⁶ In a similar study, samples harvested at 3 hours after treatment revealed histological findings of disorganization of matrix structure and increase in degraded collagen.²⁷ Gene expression of type I collagen and matrix metalloproteinase 1 was increased at 6 weeks after SWT.²⁷ In these studies the degraded collagen and disorganization of the collagen at 3 hours after treatment warrant some concern about a possible detrimental effect of SWT. However, these studies were done in normal pony tendon and ligament, and one would expect these findings to already be present in injured soft tissues.

The most common application and the greatest amount of SW research in the horse have related to tendons and ligaments.

SUSPENSORY DESMITIS

To study the effects of SWT in horses, ultrasonography was used to monitor healing in two studies of suspensory ligaments after collagenase-induced desmitis.^{28,29} In both studies, ultrasonographic measurements showed the defects healed faster in the SW-treated groups. Different outcomes were evaluated histologically in each study, but a positive effect of SWT was found in both studies. In forelimbs treated with SWT, there was increased metachromasia consistent with increased production of extracellular matrix in the SWT group.²⁸ In hindlimbs there were more newly formed small collagen fibrils in the SWT group.²⁹ The exact mechanisms by which these outcomes occur are not fully understood and it is unknown if the differences between treated and controls would result in a stronger outcome or less recurrence of injury in horses with suspensory desmitis. Immunocytochemical evaluation of suspensory ligaments treated by SWT showed increased TGF- β 1 after treatment.²⁹

Clinical response to SWT is consistently better in forelimbs than in hindlimbs. In a retrospective clinical study of horses with forelimb proximal suspensory desmitis (PSD) managed with 2000 pulses at 0.15 mJ/mm^2 , 61.8% of horses with desmitis were in full work by 6 months, and 55.9% were still working at 1 year.³⁰ Editors' note: However, it must be borne in mind that many horses with forelimb PSD respond well to conservative management of

rest alone (see Chapter 72). Of horses with hindlimb suspensory desmitis, 40.9% were in full work at 6 months, but only 18.2% were in full work at 1 year.³⁰ Results using RPW therapy in horses with forelimb or hindlimb lameness of at least 3 months' duration before treatment associated with PSD were remarkably similar.^{31,32} Response was related to lesion severity determined ultrasonographically. At a recent equine practitioners' meeting,* the consensus on outcome was similar to these reports. Many practitioners do not consider horses with hindlimb suspensory desmitis to be good candidates for SWT alone. A combination of SWT and plantar fasciotomy to relieve alleged pressure on the proximal aspect of the suspensory ligament and to stimulate healing of the defect may provide a better prognosis. Horses with body and branch desmitis are also commonly treated and thought to have acceptable outcomes; however, there have been no controlled clinical trials, and information is anecdotal.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS

There are two studies that have evaluated the short-term effect of SWT on collagenase-induced superficial digital flexor (SDF) tendonitis in the midmetacarpal region.^{33,34} Ultrasonographically, the treated and control groups were similar throughout the studies. Histologically, the treated tendons were more "mature," indicating that the healing process was occurring at a faster rate. Treated tendons had more parallel collagen fibers than controls in one study, and treated tendons had increased neovascularization in the other study. In both studies there was an initial decrease in inflammation associated with SWT, but in neither study was tendon strength evaluated. A notable finding after SWT of tendonitis is the rapid improvement in clinical appearance. The peritendinous inflammation that results in the "bowed" appearance decreases quickly after SWT. One must be careful not to interpret that as tendon healing. The echogenicity and fiber alignment of the tendon injury must be monitored with ultrasonography.

ADDITIONAL APPLICATIONS

Osteoarthritis

Osteoarthritis (OA) of the distal hock joints was one of the first applications of SWs in the United States. In an early study of 74 horses with "bone spavin" refractory to medical therapy given SWT using a single high energy (0.89 mJ/mm^2) treatment of 2000 pulses, 59 (80%) horses improved by 90 days.⁴ There are horses with OA of numerous joints that anecdotally have improved after SWT.³⁵ However, responses are mixed. In some horses, lameness decreases for a few months after SWT, whereas in others there is no change. I cannot find a logical explanation. SWT was evaluated experimentally in an osteochondral fragment-exercise model of OA of the middle carpal joint (see Chapter 84).³⁶ In treated horses, there was a decrease in total protein concentration in synovial fluid and less lameness on day 28 compared with controls.³⁶

*Applying Regenerative Therapies for Tendon and Joint Caused Lameness of Horses, Bonn, Germany, October 6-7, 2008.

Navicular Syndrome

Clinical signs in horses with navicular syndrome may improve after SWT.^{37,38} In 16 horses with long-term follow-up examination treated with 1000 pulses through the frog and 1000 pulses from between the heel bulbs under general anesthesia at 0.89 mJ/mm², masked video analysis from before and 6 months after treatment showed 56% of horses improved at least 1 lameness grade.³⁷ Owners reported 69% of the horses returned to the previous level of activity. There was no comparative control group. In another study, all 26 horses treated under general anesthesia with 3000 pulses at 0.56 mJ/mm² were free of lameness at 6 months.³⁸

Navicular syndrome is complex, and as diagnostic techniques have improved, we now know that pain can originate from the deep digital flexor tendon, navicular bursa, the collateral sesamoidean or distal sesamoidean impar ligaments, the navicular bone itself, or other structures. SWT is indicated for horses that do not adequately respond to medical therapy and corrective shoeing. However, it must be recognized that navicular syndrome is a progressive disease, and SWT is not a cure.

Collateral Ligament Injury of the Distal Interphalangeal Joint

There is a recent report of the use of SWT or RPW therapy for the treatment of horses with collateral ligament injuries of the distal interphalangeal joint. There was no significant difference in outcome for horses managed by box rest and controlled exercise alone or combined with SWT or RPW therapy.³⁹

Back Pain

SWT has been used for numerous causes of back pain, including impinging dorsal spinous processes, OA of articular facet joints, and soft tissue injury. There are two approaches to therapy for back pain. First is the treatment of specific sites of bony pathology identified by radiography, scintigraphy, and ultrasonography. Both sides of the back are treated with 35- and 80-mm probes (designed to treat equine backs; Equitron, Sanuwave Inc., Marietta, Georgia, United States) at 0.15 mJ/mm². Most horses improve after one or two treatments. A dose of 50 pulses/cm of bone "sclerosis" was suggested.²³ Second, horses that have back pain without specific skeletal pathology may respond to treatment of the muscle with SWT.^{2,40} The 35- and 80-mm probes are moved along the dorsum of the horse. When the horse shows a painful reaction or muscle fasciculation, 80 to 100 pulses are applied at the site. There are anecdotal reports of SWT used for treating sacroiliac disease; an 80-mm probe may reach the dorsal sacroiliac ligaments but is unlikely to reach the sacroiliac joints per se.

Some horses with OA of the cervical articular facets (see Chapter 53) respond well to SWT, and others have a limited response. It is important to identify the specific facet joint to be treated and focus the SWs on the facet similarly to an injection into the joint. Two to three treatments at 2- to 3-week intervals are performed. If response is acceptable, then the treatment is repeated as needed.

Therapy Planning

When considering the application of SWs, obviously an accurate diagnosis is imperative. Next one needs to consider whether one can and should focus SWs on the

pathology. SWs will not penetrate the hoof wall. Bone can be treated; however, 70% of the energy is lost in the bone. Therefore little energy is available on the opposite side of the bone. Most focused generators have a series of standoffs that adjust the depth of penetration. Any site that can be seen ultrasonographically can be treated with SWs, and ultrasonography can be used to measure the required depth if necessary. RPWs are different from the more powerful focused SWs in that the energy of the wave decreases proportional to the square of the depth; thus the depth of penetration is limited.

A three-dimensional treatment plan should be used to apply SWs to the full width and depth of the injured area.²³ For example, to treat a horse with PSD, the entire width and depth of the proximal aspect of the suspensory ligament are treated by using two probes, one with a 20-mm and the other with a 35-mm focal distance (and a commonly used generator; Equitron, Sanuwave Inc.). From the palmar midline, both probes are used to administer SWT to the axial aspect of the suspensory ligament, and then the 20-mm probe is used from oblique angles just palmar and axial to both splint bones to treat the remaining abaxial aspects of the ligament. The probes are slowly moved around the treatment area when applying SWT. This should expose the entire proximal suspensory ligament and the palmar/plantar aspects of the third metacarpal or metatarsal bones to the SWs.

SWs will completely reflect at an air interface, and it is important to avoid air interfaces during treatments near the thorax and abdomen. The pressure wave will be reflected and can cause hemorrhage at the interface. It is important to have the generator in good contact with the skin surface. Typically, the hair is clipped with a No. 40 blade. To obliterate the air interface found between the probe and skin, ultrasound coupling gel is the best agent to use, but water, mineral oil, and petroleum jelly are all suitable. It is best to slowly move the probe in the direction of the clipped hair, and then move back up and down again, with care taken to recoat the area with the gel. The convex radial generators may get air bubbles in the concavity, making coupling difficult.⁴¹

Combination therapies are frequently used to treat soft tissue injuries. Platelet-rich plasma and pig's urinary bladder matrix (ACellVet, Webster Veterinary Supply, Sterling, Massachusetts, United States) injected intralesionally in combination with SWT may result in some additive effects. My personal experience is favorable when I use a combination of ACellVet in horses with SDF tendonitis at the time of the first of three SWTs. The direct effect of SWs on stem cells in vivo is unknown. For this reason, when used together, I suggest SWT should precede the injection of stem cells, and the next SWT should be delayed for 3 weeks. Editor's Note: Since the effect of SWs on stem cells is unknown and given that stem cell therapy is still unproven and rather expensive, it may be best to select either SWT or stem cell therapy rather than combine the modalities.

Potential Complications

Very few complications are seen with SWT. There are dose-related effects, and it is possible to overtreat an area. With most commonly available devices, there are general guidelines to assist the veterinarian to calculate the appropriate dose. Transient swelling at the treatment site is occasionally

noted and is more commonly seen when using RPW devices. White hairs may develop at the treatment site. As noted above, air- or gas-filled structures should be avoided. What is the effect of SWs on a physis? Some say it stimulates growth, whereas others say it inhibits growth. Studies in rabbits showed SWs can lead to premature closure of a physis; however, this work has not been repeated in horses.⁴²

Analgesia

Analgesia has been a welfare concern since the beginning of SWT in the horse. There are concerns that analgesia after treatment may result in worsening of an injury when a horse returns to work. In vivo evaluation of skin sensation after both focused SWT and RPW therapy showed some

analgesia for 48 hours after treatment.⁴³ There was no analgesia of the nerve field after the application of SWs and RPWs directly to the palmar digital nerve; thus it was concluded that analgesia was a local effect. In horses with unilateral navicular syndrome and OA where analgesia was measured as a change in increase in peak vertical force after treatment, analgesia from SWT was identified that peaked at 48 hours after application.⁴⁴ In a similar study using horses with unilateral navicular syndrome and RPWs, no analgesia was found.⁴⁵ The RPWs may not reach the depth sufficient to affect pain sensation from the palmar foot structures. Many racing and horse show jurisdictions have specific rules about SWT, and they should be consulted.

Lameness in the Sports Horse

SECTION 1

Poor Performance

Chapter 97

Poor Performance and Lameness

Sue J. Dyson

Horses may be presented to a veterinarian because of a change in performance or behavior or failure to live up to the expected level of performance, rather than because the rider or trainer has recognized overt lameness. Many of these horses do have musculoskeletal problems. The type of complaint often reflects the discipline in which the horse is used. For example, an event horse may be assessed because it has started stopping at drop fences, whereas a dressage horse may be evaluated because it takes uneven steps behind in passage or piaffe.

CHALLENGE OF ASSESSMENT

This type of horse presents the veterinarian with a diagnostic challenge that may involve assessment not only of the horse, but also of the horse and rider together and the rider's ability. Such an assessment requires knowledge of the sport in question and an ability to recognize when the problem is a lack of athletic ability or a mental problem rather than a pain-related musculoskeletal disorder or some other pathological condition, such as an upper airway disorder. The assessment also requires good knowledge and appreciation of how horses normally move and the variations among different breeds and types and an ability to recognize subtle changes in gait, such as a slightly reduced lift to the stride or stiffness in movement of the back. The assessment requires basic knowledge of equine locomotion and how gait may be modified by pain and also requires the ability to recognize when a rider may actually be creating the problem. Training methods and style of riding may contribute to the development of lameness.

This section sets out to discuss some of the different problems that may be encountered and the types of conditions that may be the cause of poor performance and to suggest some methods of approach to diagnosis. These may

vary to some extent depending on whether the clinician is dealing with a competent professional rider or trainer or an inexperienced or even experienced amateur who lacks ability.

HISTORY

It is essential to obtain a comprehensive history to determine whether the horse has genuinely performed better previously at this level of competition, or moved better, and precisely what changes have been observed. It is important to listen carefully to the owner to properly understand the perceived problem, however small it might be. This is particularly important if the clinician does not have prior knowledge of the horse.

Determine the answer to the following questions:

1. What are the age and training history of the horse?
2. Does the horse have the musculoskeletal coordination and strength to do what is being asked?
3. Has the horse recently moved up a level of competition? Does the horse have the confidence or athletic ability to cope?
4. What is the current work program? How does this vary from day to day? Is the horse allowed turnout?
5. Has a recent change in the work pattern or intensity or some other change in management occurred?
6. Has the bit been changed?
7. Did the horse sustain a fall or any other trauma before the onset of the problem?
8. Has a recent change in the rider or trainer occurred?
9. Has an alternative rider been tried?
10. Has the horse ever exhibited clinical signs consistent with exertional rhabdomyolysis?
11. Under what circumstances is the problem apparent?

Viewing videos of the horse when it was performing normally sometimes can be helpful to compare with the findings of your own clinical evaluation. If the horse has recently changed ownership, comparing video recordings of the horse ridden by the previous rider and by the current rider can be useful to determine whether a change in riding style or training techniques may be responsible for making a previously subclinical problem become symptomatic, or to determine if the problem could be related directly to the manner in which the horse is being worked.

The types of clinical problems that may be encountered are listed in [Box 97-1](#).

BOX 97-1

Types of Clinical Problems

- Not jumping as well: knocking down rails. This may be pain related or may be caused by the rider presenting the horse poorly to the fence.
 - Not jumping as well: stopping. This may be a horse or rider confidence or ability problem, or may be pain related.
 - Not making distances in combination fences. This may occur because the horse is landing too steeply, saving one or both front feet and therefore having too much ground to make up, or through lack of push from behind, reflecting a hindlimb lameness. Alternatively, if the horse is presented poorly to the first element of the fence, the subsequent elements become increasingly difficult.
 - Reluctance to land leading on a specific leg. This can reflect a forelimb or less commonly a hindlimb lameness. Peak ground reaction forces at landing are significantly greater in the trailing forelimb than in the leading forelimb¹; therefore a tendency to land with the right forelimb leading is most likely a reflection of right forelimb pain. However, stress on the suspensory apparatus is greater in the leading forelimb; therefore in association with suspensory pathology a horse may avoid landing with the affected limb leading.
 - Napping (resistance) on the approach to a fence off a turn. Nappiness may be pain related or behavioral.
 - Not jumping straight (e.g., jumping to the right), with a tendency for the hindlimbs to drift toward the direction in which the horse is jumping (to the right). This usually reflects pain or weakness in the ipsilateral hindlimb of the side to which the horse is jumping. Less commonly the problem may be caused by reluctance to land on the contralateral forelimb (e.g., the left).
 - Loss of hindlimb power. This may be caused by back pain or hindlimb lameness. Less commonly it may be the result of low-grade hindlimb ataxia.
 - Change in the shape the horse makes over a fence—for example, loss of bascule (jumping with a rounded arc over a fence). This may reflect back pain or forelimb or hindlimb lameness, or possibly gastric ulceration. It may also reflect the way in which the horse is presented to the fence.
 - Rushing fences. This can be the way an excitable horse always jumps, but if the horse used to jump normally, rushing the fence usually reflects a painful problem. However, if the horse has been stopping for whatever reason and has been chased to the fences, it will inevitably rush. If a horse is overly restricted by the rider's hands it may also try to rush to escape.
 - Loss of action. This can reflect the way in which the horse has been ridden and trained. Some loose, free-moving young dressage horses become much more restricted in their stride when ridden exercise is commenced. An apprehensive rider may restrict a potentially exuberant horse. A bored horse, particularly with a Warmblood mentality, may just switch off and refuse to go forward freely and loosely. Loss of action also may reflect forelimb or hindlimb lameness or back pain.
 - Stiffness. Stiffness should be evaluated carefully to differentiate loss of action and back stiffness from restriction of gait caused by a bilateral forelimb or hindlimb lameness.
 - Inability to perform medium or extended trot. Unless a horse is properly balanced with adequate hindlimb impulsion, it cannot perform medium or extended trot. Horses vary considerably in the ability to collect and extend. In general the Thoroughbred breed has much less natural ability than many of the Warmblood breeds. Some horses have to learn how to perform a medium and an extended trot and must first develop sufficient muscular coordination and power before they are able to do so. However, if a horse was previously able to work in medium and extended paces and now cannot do so, or if the rhythm becomes irregular, this can reflect forelimb or hindlimb lameness or back pain.
 - Inadequate hindlimb impulsion in trot, with a tendency to break to canter if asked to work harder. This usually reflects hindlimb lameness.
 - Difficulty in performing specific dressage movements—for example, right half pass. This often reflects a back or sacroiliac joint region problem or hindlimb lameness.
 - Tendency to become disunited behind in canter. This usually reflects hindlimb lameness. However, it is important to recognize that young horses can find maintaining true canter difficult, sometimes just in one direction, or sometimes in both directions. This often can be overcome by training and development of muscular strength and coordination. Some trained horses that canter true when ridden may become disunited when cantering on the lunge. Hindlimb lameness may predispose to a horse becoming disunited. If the problem occurs to a similar extent on both reins, it often reflects a bilateral problem, but if it occurs on only one rein, the problem is more likely to be unilateral.
- Although the canter stride is initiated by the trailing hindlimb, which bears weight alone, the stance time, peak vertical ground reaction forces, and range of motion of the proximal limb joints are higher in the leading hindlimb.^{2,3} Therefore if the horse consistently becomes disunited on the left rein, this is likely to reflect discomfort in the leading left hindlimb.
- Late flying changes, or difficulty in changing from right to left or from left to right. This usually results from hindlimb lameness.
 - Inability to maintain a consistent rhythm in piaffe, passage, or canter pirouettes. This usually reflects a hindlimb lameness.
 - Unevenness in certain movements. Mild irregularities in rhythm may be detectable only in certain movements—for example, left half pass and right shoulder in. Such irregularities can reflect forelimb or hindlimb lameness or may be induced by the rider overrestricting with the hand and not creating sufficient hindlimb impulsion. Dressage riders often refer to *bridle lameness*, implying that lameness is not true because it cannot be detected when the horse is trotted in hand or lunged. This usually is a misnomer, because most bridle- or rein-lame horses have a genuine lameness, which may be apparent only when the horse is ridden.
 - Crookedness, or reluctance to take the bit evenly on the rider's left and right hands. This can result from a training problem or can be caused by lameness or unwillingness to accept the bit because of oral pain. Less commonly it may reflect temporomandibular joint pain.
 - Taking unequal-length strides behind in walk, despite appearing sound in all other gaits. This can be seen in some otherwise normal horses that show no response to systemic administration of analgesic drugs. This syndrome is generally seen only when the horse is ridden and in some horses is apparent only when the horse walks on the bit, and not when it walks on a long rein. It is characterized by a shortened cranial phase of the stride. Local analgesic techniques from the foot to the coxofemoral joint usually have no effect on this gait. Radiographic, ultrasonographic, and nuclear scintigraphic examinations are usually unrewarding. Alternatively, irregular strides may reflect hindlimb lameness also seen at other gaits.
 - Lameness apparent only when the horse is working to a contact, on the bit, and not when worked on a long rein. Problems in these horses can be difficult to solve. Some reflect a forelimb lameness, upper forelimb muscular pain, or caudal cervical pain.
 - Inability to engage the hindlimbs on the forehand. This usually reflects hindlimb lameness or back pain.
 - Hanging, or on one line. This often reflects hindlimb lameness or forelimb lameness in a Standardbred.
 - Loss of power cross-country. This may be caused by subclinical exertional rhabdomyolysis, discomfort associated with superficial digital flexor tendonitis, or other causes of lameness. Alternatively, the horse may have acute-onset back muscle pain.
 - Reluctance to jump drop fences. This can be a rider or horse confidence problem, but it also may be caused by forelimb lameness or back pain.

(Continued)

BOX 97-1

Types of Clinical Problems—cont'd

- Cold-backed behavior when tacked up or first mounted. This is manifest by the horse tensing, roaching the back, sometimes freezing and refusing to walk forward, and then sometimes exploding into a series of violent bucks. Often this abnormal behavior stops within a few minutes, and the horse then works completely normally.

Cold-backed behavior can be unrelated to pain and may be a problem initiated by pain, which then becomes a behavioral response. Such behavior may reflect fear, especially if a rider has fallen off several times, and less commonly is associated with chronic pain because of a rib fracture, fractured sternum, or nerve-related pain.

The behavior may be precipitated by rapidly tightening the girth, especially if the girth has an elastic inset.

Cold-backed behavior is generally manageable by an experienced rider, but such behavior is potentially dangerous to a nervous or inexperienced rider. Affected horses should be tacked up slowly and the girth tightened progressively, walking the horse forward each time. The horse should be lunged and made to go forward at the trot and the canter before being mounted. The rider should be legged up onto the horse and should not attempt to mount from the ground.

Horses with cold-backed behavior may improve with careful management but should never be trusted completely.

- Bucking. Bucking behavior can be similar to cold-backed behavior, or it may occur only after the horse has been ridden for a period. Although the horse may appear to buck with a flexible back, primary back pain is sometimes the underlying cause. Back pain secondary to hindlimb lameness may also result in bucking. Bucking can be a behavioral problem unrelated to pain.
- Bucking and kicking out to one side is often a manifestation of sacroiliac joint region pain.
- Rearing. Rearing is often part of nappy or resistant behavior: the horse tests the rider. Relatively rarely is rearing associated with a pain-related problem such as sacroiliac region pain.
- Bolting. Bolting may result from pain of any cause (e.g., bilateral hindlimb proximal suspensory desmitis) or may be a behavioral problem.

- Tendency for the saddle to slip to one side. This may be because of the rider's inability to sit straight, a poorly fitting saddle, or unilateral hindlimb lameness. The saddle usually slips to the side of the lame hindlimb.
- Reluctance to work on the bit. Difficulties in working on the bit may be one of the first signs noted by a rider when the horse develops a minor musculoskeletal problem involving the back or limbs, or a mouth problem.
- Head-shaking behavior when ridden. There is a poorly understood syndrome in which horses head-shake generally only when ridden, although if the horse is severely affected the behavior may also be apparent on the lunge and occasionally in the stable. Such horses are usually worse in the summer months. Affected horses sneeze frequently and may strike out with a forelimb or repeatedly try to rub their nose on one or both forelimbs. The behavior may be controlled in some horses by placement of a net over the horse's nostrils. Mildly affected horses may perform normally when jumping and may show signs only when worked on the flat. Severely affected horses may be virtually impossible to ride.
- Unwillingness to work. This may be behavioral or pain related. Warmblood breeds in particular are strong-willed horses that easily recognize when their rider is not competent enough, and rapidly a vicious circle can ensue. However, reluctance to work equally may reflect lameness or back pain.
- Nappy (resistant) or evasive behavior. This may reflect pain or the dominance of the horse over the rider. Although some horses have a compliant temperament and never take advantage of an incompetent handler or rider, other horses rapidly recognize lack of ability, or apprehension of the rider, and develop resistant or awkward behavior.
- Progressive agitation with work, with or without loss of action. This may reflect the horse's temperament or pain caused by exertional rhabdomyolysis, for example.
- Episodic complete loss of rhythm and lack of synchronization of movement of all limbs. This may reflect a multilimb lameness, but it may also be an evasion or reflect tension. If the horse puts its head up and hollows its back, maintaining a regular rhythm is difficult. Working the horse in draw reins, changing the work environment, and using sedatives or analgesic drugs can help to differentiate a pain-related problem from an evasion.

Investigation of this type of horse is time-consuming and usually requires repeated clinical examinations, together with ancillary diagnostic techniques. Ideally the horse should be in full work at the time of the investigation. The horse must be assessed in its entirety, including full visual appraisal and palpation at rest, evaluation of the horse moving in hand and on the lunge on soft and hard surfaces, and assessment of the response to flexion tests. Ridden exercise is crucial.

CLINICAL ASSESSMENT

It is generally essential to see the horse ridden by the regular rider, performing the movements that are causing difficulty. If the veterinarian does not feel competent to judge the rider and the influence the rider may be having on the problem, the assistance of a professional rider or trainer may be necessary. However, it is important to recognize that not all so-called "experts" are truly experts, and the advice of a misguided professional may serve only to muddy the waters.

It is important to appreciate the profound influence that back pain arising from the thoracolumbar or sacroiliac regions can have over the horse's entire manner of moving.

Back pain not only may induce back stiffness, but also may result in the horse holding itself tensely and not accepting the bit properly, with a restriction in stride length and reduced lift to the stride in all limbs. Bilateral hindlimb proximal suspensory desmitis may have a similar effect.

Clinical assessment of back pain is not easy. A normal horse should be able to flex and extend the thoracolumbar spine repeatedly in the sagittal plane and flex from side to side with ease, without inducing tension in the epaxial muscles. Holding the back stiffly, sinking on the hindquarters to avoid extension, and showing evidence of muscle fasciculation or spasm may indicate pain. Alteration of facial expression and a tendency to bite or kick out may also reflect pain. However, some nervous, thin-skinned horses guard the back and do not flex normally unless they are relaxed completely. Some stoical cob-type horses show little response at all. Some horses respond to digital palpation, whereas in others firmer pressure must be applied, using, for example, the closed tips of a pair of artery forceps to induce flexion and extension of the back.

In a normal horse at the trot and canter appreciable up-and-down movement of the back occurs, along with swing from side to side, with an easy swinging movement of the tail. The degree of movement is to some extent

determined by the horse's natural athleticism. The degree of movement often is reduced with back pain. The degree of restriction of movement reflects the temperament of the horse and hence its reaction to pain and the severity of the pain. Clinical signs of back pain may be subtle unless the horse is assessed while it is ridden. Restricted back mobility may be more obvious when the rider sits continuously in the saddle, in sitting trot and canter, compared with when the rider sits lightly, or rises up and down in the trot. Movement of the tail may be restricted. The restricted movement of the back may be much more obvious to a rider than to an observer and may induce back pain in the rider. Further investigation of thoracolumbar and sacroiliac pain is discussed elsewhere (see Chapters 50 through 52).

It is important to recognize that many horses with hindlimb lameness show signs only when the horse is ridden. The modification of stride variables because of hindlimb lameness is much less than for forelimb lameness. The diagonal on which the rider sits in rising trot often substantially influences the lameness. Lameness is usually most obvious when the rider sits on the diagonal of the lame limb and may be unapparent on the other diagonal. The horse may deliberately try to make the rider sit on the nonlame diagonal. Low-grade irregularities in gait may be most apparent when the horse changes direction when performing small figures of eight (e.g., loss of rhythm, swinging the hindquarters to the outside of the circle, crossing the inside hindlimb in underneath the body during protraction, coming slightly above the bit) or when decelerating from canter to trot or from trot to walk (e.g., failure to "sit down" behind and engage the hindlimbs), or may be manifest as hopping into trot from walk. Subtle delayed release of the patella may be apparent only as a horse decelerates.

Recurrent low-grade equine rhabdomyolysis may occur almost every time an affected horse is ridden, without any of the classical clinical signs of tying up. Measurement of serum concentrations of creatine kinase and aspartate transaminase reveals elevation of both. Some of these horses have increased radiopharmaceutical uptake in the affected muscles in bone phase images if examined using nuclear scintigraphy.

It is often necessary to compare the horse's performance when ridden by a different rider, bearing in mind that riders with varying abilities can make horses appear different, and riders of differing weights and ability to follow the rhythm can make a great difference in the horse's gait. A good rider can make a slightly nappy horse go forward freely, with a totally rhythmical stride, whereas a less competent rider may be unable to ride the horse through, and the horse may take uneven steps behind because it is not going forward enough. A heavy rider or a rider who is unable to ride properly in balance may induce hindlimb lameness. The same horse ridden by a lighter rider may be completely sound. A horse that evades the bit and runs along with its head in the air may take irregular steps in front and behind and appear stiff in the back, especially if a rider attempts to make the horse work on the bit. The same horse, when encouraged to submit and work on the bit when ridden by an expert with draw reins, may appear completely different, relaxing the back, stepping under more from behind and becoming much more rhythmical. It is often necessary to separate the owner from

the horse diplomatically to assess how the horse responds to a skilled rider over several days.

It is also important to recognize that inappropriate work patterns on the flat or over fences actually can induce musculoskeletal pain, which may progress to chronic lameness. For example, repeatedly placing the horse too close to a jump (putting the horse in deep), which also alters the bascule over the fence and the way in which the horse lands, may predispose the horse to patellar ligament soreness. This may alter the horse's way of moving and predispose to the development of pain elsewhere. In the early stages the problems potentially may be managed with a change in work program and methods of training the horse. However, long-term problems may be more difficult to resolve satisfactorily.

Paradoxically, it may be helpful to see a usually well-ridden horse with a subtle performance problem ridden by a less clever rider. The professional rider may be making subtle adjustments to the gait inadvertently and thereby masking gait irregularities reflecting low-grade lameness.

The fit of the tack and its suitability must be evaluated. The veterinarian should not assume that because the saddle was fitted by a professional saddle fitter that it necessarily does fit. The position of the bit in the mouth, the size of the bit relative to the size and shape of the mouth, and the suitability and the severity of the bit should all be assessed. The mouth should be inspected carefully to ensure that no lacerations of the tongue, gums, or corners of the horse's mouth have occurred and that the teeth have no sharp points or hooks.

In some instances the horse may appear to be clinically normal, and it is necessary to try to establish whether the complaint is indeed pain related. In my experience, phenylbutazone is the most effective analgesic drug for trying to determine whether a problem is pain related. The drug must be given at a high enough dose (minimum 4.4 mg/kg twice daily) for long enough (at least 7 days if the horse does not respond within 2 to 3 days). A comparison with records of the horse's attitude, behavior, and action before, during, and after treatment should be assessed as objectively as possible. A positive response confirms the presence of a pain-related problem, whereas a negative response does not definitively exclude a pain-induced problem. The potential exists to create a placebo effect for the rider, and in selected horses, "blinding" the rider to the treatment may be worthwhile.

If the problem seems to induce considerable anxiety and tension when the horse is worked, mild tranquilization with acepromazine or sedation with detomidine can be helpful to determine if the problem is pain induced or reflects tension. The tension actually may be induced by the rider or the environment in which the horse is worked. Working the horse in a different situation with another skilled rider can be helpful.

If the horse is fresh and exuberant, minor gait abnormalities can be difficult to assess, especially in a big moving dressage horse. In these circumstances mild sedation can be useful.

It is important to try to determine if a problem reflects pain or weakness caused by a neurological problem. Low-grade hindlimb toe drag may reflect a mild proprioceptive deficit rather than lameness. When in doubt, a comprehensive neurological examination should be performed (see

Chapter 11). This is particularly important in areas (North and South America) where equine protozoal myelitis occurs. In other countries it is important to establish whether the horse has ever been to America.

It is also important to recognize that some horses that are mild wobblers, with mild hindlimb gait abnormalities seen when moving loose or in hand, may actually move loosely and freely when ridden, with apparently good coordination, and perform rather well in low-level dressage and other competitive disciplines despite a problem. However, such horses usually lack strength and coordination to perform more advanced dressage.

Diagnostic Analgesia

In some horses, taking an educated guess about a potential source of pain and medicating the suspect joints with, for example, triamcinolone acetonide and assessing the response to medication (so-called “diagnostic medication”) may be necessary. For example, in a dressage horse taking uneven-height steps behind in piaffe, or failing to maintain a regular two-time rhythm in piaffe, medicating the distal hock joints may be worthwhile. However, it is necessary to recognize that a negative response does not definitively exclude distal hock joint pain as the primary problem. Paradoxically, in some horses the response to intraarticular analgesia may be better than the response to intraarticular medication, whereas in others the response to medication is better than the response to analgesia, even in the absence of radiological abnormalities.

Frequently through careful clinical evaluation of the horse, a low-grade, bilateral, symmetrical lameness can be identified that can be investigated further through local analgesic techniques and then appropriate imaging modalities. With low-grade bilateral forelimb lameness, blocking both front feet simultaneously, for example, may be more useful than blocking one at a time and then assessing the change in the horse’s overall way of moving. With poor hindlimb propulsion, blocking the region of the origin of both hindlimb suspensory ligaments may be more useful than blocking one at a time. In some horses concurrent forelimb and hindlimb lameness may be detected. This may be manifest as lack of athleticism or animation, lack of power, or merely reduced stride length. Alternatively, back stiffness may be identified, requiring further investigation by radiography, nuclear scintigraphy, and ultrasonography.

Diagnostic Imaging

Thermographic evaluation, particularly of the neck and back, is thought by some to be helpful in diagnosing low-grade performance abnormalities (see Chapters 25 and 95). However, others have found thermography much less rewarding. It is vital to recognize the normal thermographic patterns, the responses to exercise, and the many other external factors that may influence the results.

In horses in which no obvious gait abnormalities can be identified or in which subtle changes are noted that cannot be investigated further by local analgesic techniques, performing a comprehensive nuclear scintigraphic examination of the horse may be helpful (see Chapter 19). However, interpretation of the results can be notoriously difficult, because areas of IRU are not necessarily synonymous with pain, and not all musculoskeletal problems are

associated with IRU. For example, bilateral proximal suspensory desmitis may result in a slightly restricted and stiff hindlimb gait, with or without stiffness of the back, but nuclear scintigraphic examination findings may be normal. Great care must be taken not to overinterpret the results of scintigraphic examination. Results must be correlated carefully with the clinical signs, the responses (where possible) to local analgesic techniques, and the response to diagnostic medication.

Gastroscopy may be valuable to determine the presence of gastric ulceration. Alternatively the response to medication with omeprazole can be assessed.

Evaluation of gait and other aspects of performance on a high-speed treadmill are discussed in Chapter 98.

COMMON PERFORMANCE PROBLEMS

The most common causes of poor performance not related to readily recognizable overt lameness are listed in Box 97-2.

These horses are time-consuming to investigate, often requiring a multifaceted approach to diagnosis. It is important to recognize that the failure to perform optimally may be the result of several problems, and recognition of all of

BOX 97-2

Common Performance Problems

Possible Clinical Problems

- Bilateral foot pain
- Bilateral fetlock pain
- Bilateral proximal suspensory desmitis, forelimb or hindlimb
- Bilateral carpal pain
- Thoracolumbar or sacroiliac pain
- Intermittent upward fixation of the patella or delayed release of the patella
- Bilateral distal hock joint pain
- Tying up

Rider-Induced Problems

- Handbrake on (i.e., too much restriction by the rider’s hands) and no legs
- Overweight; inability to follow the rhythm
- Lack of confidence
- Overhyped rider being too restrictive
- Misunderstanding of how to achieve “on the bit”
- Poor eye for a stride; therefore repeatedly placing the horse in less than ideal positions for take off for a fence, making the jump more awkward or necessitating more effort
- Sitting crookedly
- Lack of rapport with the horse
- Trainer-induced problem
- Monotonous training program with no variation

Horse Problems

- Lack of ability
- Unsuitable temperament
- Loss of confidence
- Lack of rapport with the rider
- Staleness
- Lack of focus in a dual-purpose breeding stallion and competition horse
- Inconsistency of a mare

these may be crucial to successful management. Determination of all the postulated sites of pain causing poor performance is based on an assessment of a detailed history of performance; the results of palpation including the response to stimulation of acupuncture points; evaluation of the horse moving in hand, on the lunge, and ridden, both when work is first initiated and later in the work program; and the response to flexion tests and chiropractic assessment of joint mobility, sometimes combined with

assessment of the response to local analgesic techniques. Although it is often essential to see the regular rider riding the horse, separating the horse from the rider for several days can be helpful, particularly with horses ridden by amateurs or semiprofessionals. It is essential to have access to adequate facilities to see the horse ridden (or driven) properly on a daily basis and to be able to perform local analgesic techniques and then reevaluate the horse ridden or driven under the same circumstances.

Chapter 98

Experiences Using a High-Speed Treadmill to Evaluate Lameness

Benson B. Martin Jr., Sue J. Dyson, and Mike W. Ross

The advent of the high-speed treadmill has led to many advances in evaluating equine poor performance in exercise physiology, gait analysis, cardiac disease, and lameness diagnosis.¹⁻⁵ This chapter describes our experience using a high-speed treadmill for lameness evaluation in the performance horse.

Lameness has been implicated as a cause of poor performance in several studies involving a complete physical examination, lameness examination, and where possible a high-speed treadmill examination.¹⁻³ In one study, 74% of horses were found to have lameness as a component of poor performance.¹ In another study, in which horses with no apparent history of lameness were examined because of poor performance, clinically important lameness in 23.9% of horses precluded a high-speed treadmill investigation.² In a third study, 4.3% of horses sound enough to undergo a high-speed treadmill examination for poor performance were clinically significantly lame after high-speed treadmill exercise.³

In our experience, convincing trainers and owners that lameness is a cause for poor performance can be difficult. Several studies using a shoe model to induce lameness to assess the metabolic cost of pain related to lameness suggested a trend that pain related to lameness may not increase the metabolic cost of exercise, but it does increase the heart rate in response to pain.⁶⁻⁸ However, another study suggested that a metabolic cost of pain and exercise does occur.⁹ Pain may alter a horse's ability or willingness to perform up to expectations or previous performance levels.¹⁰

CRITERIA FOR CASE SELECTION

The most common criterion for a treadmill lameness examination is lameness that occurs at only high speeds or after

an extended period of exercise. The treadmill examination is used most commonly in Standardbred (STB) racehorses or endurance horses. However, a treadmill lameness examination can be used in any breed or discipline, although a horse in which lameness is apparent only when the horse is ridden may be unsuitable.

Horses in which a complete lameness investigation, including diagnostic analgesia and appropriate imaging technologies, fails to reveal a diagnosis are potential candidates for treadmill lameness examination. Additional candidates include horses that require considerable work at low, medium, or higher speeds before the lameness becomes apparent, such as endurance horses or STB racehorses. A treadmill lameness examination also may be useful in horses that are fractious or otherwise pay little attention when jogged in hand or ridden. Horses must pay close attention when trotting on a treadmill and therefore have a more even, rhythmical, relaxed gait that is easier to evaluate.

HISTORY

Important historical facts need to be ascertained. Some questions are general, and some are use related. Some may need to be repeated in a different order to elicit an accurate answer. Questions may include those listed in Box 98-1.

EQUIPMENT

The treadmill must have a speed of at least 7 to 10 m/sec. Most horses will not canter until the speed exceeds 7 m/sec. Lameness is usually evident at lower speeds, but occasionally it is necessary to see a horse trot at up to 7 m/sec for lameness to become manifest. In addition, for further poor performance evaluation the treadmill needs a speed of at least 14 to 15 m/sec and the capability of being elevated to at least a 6-degree slope. Ideally the treadmill should be mounted in the ground, which is safer. In our experience clients and horses easily adapt to an in-the-ground treadmill. It is easier to use video equipment with a treadmill in the ground, rather than above the ground.

At least 4 to 5 m of space in front of, behind, and on either side of the treadmill is needed to allow for equipment, cameras, and personnel and to allow room for the horse to move off the front, rear, or side. The moving treadmill surface is relatively forgiving. In one study in which a horse had a strain gauge placed on the left third metacarpal bone, bone strain was measured as the horse galloped on a dirt track, on a wood chip track, and on a treadmill. Compared with the dirt track bone strain was 75% less when the

BOX 98-1

Questions to Ask When Determining History**General Questions**

- How long has the horse been lame?
- When do you notice the lameness?
- Does the lameness improve with exercise?
- Does the lameness become worse during or after exercise?
- Does the horse ever appear to become anxious or frantic?
- Does the horse sweat?
- Has the horse's performance level changed?
- Has the horse changed how well it performs?
- Has the horse changed the style of performance?
- Has the horse had any behavioral changes?
- Has the horse been treated for lameness?
- Has the horse been "tapped"?
- Has the horse ever had any joints treated?
- Has the horse received any intramuscular treatments?
- Has the horse received any other therapy or medication?
- How much and for how long?
- What has been the response?
- Does the horse receive any special supplements (e.g., sodium bicarbonate)?
- What type of shoes does the horse wear and why?
- Does the horse have any special shoeing or trimming and why?

Use-Specific Questions**Standardbred Racehorses**

- At what speed is the horse the worst?
- At which gait (trot or pace) is the lameness most easily seen?
- Is the horse worse on the straight or on turns?
- Is the horse worse when turned in the correct direction of the track?
- Is the horse worse when jogging?
- What is the horse's normal gait?
- Has any change in the horse's gait occurred, and what is the change?
- Is the horse on a line?
- Is the horse on a shaft?
- Does the horse get into his knees?
- Is the horse worse when jogging free legged or in full harness?
- Is the horse worse when checked up?
- Does the horse use any special gaiting equipment?
- Does the horse wear any head poles?
- Does the horse wear any other special equipment and why?

Thoroughbred Racehorses

- Does the horse bear in or out?
- Does the horse break out of the starting gate as well as before?
- Does the horse require any special bit or tack and why?
- At what speed is the lameness best seen or felt?
- Is lameness worse with or without a rider?

Endurance Horses

- How far does the horse have to go before the lameness appears (time or distance)?
- What does the lameness feel like or look like?
- Does the horse have any bruising of the feet?
- Does the horse feel or look like it is tying up?
- Does the horse sweat normally?

Dressage and Show Horses

- Is the horse worse when ridden?
- Is the horse worse on a large turn or small turn?
- Is the horse worse going up or down a hill?
- Is the horse worse when collected or on a free rein?

horse galloped on the wood chip track and an additional 75% less when it galloped on the treadmill.¹¹

Kinematic analyses include high-speed cinematography, videography, electrogoniometry, or accelerometry to quantify the movements of the limbs and torso during exercise. Kinetic analyses use instrumented shoes, force plates, and pressure-sensitive mats to measure forces that affect, arrest, or modify motion. The reader is referred to Chapter 22 and other references. Many of these systems are expensive, time-consuming, and cumbersome and require considerable expertise to use. The ideal gait analysis system provides considerable data, which are obtained easily, are visually and statistically analyzed, and are not too expensive. The system must be fast enough to assess correctly diagnostic analgesic techniques in a timely fashion and simple enough to not alter the gait of the horse.^{12,13}

Simple systems can be assembled with a digital video camera, a tripod, and a computer, using simple video editing software to review and edit the images. If a computer is not available, video editing tape decks can be used. The camera or cameras are placed perpendicular to the side and front or rear of the treadmill. Caution must be used with the rear camera. Enough light must be available for adequate video viewing (at least two 1000-W lights or equivalent).^{12,13}

The video camera should be a digital camera (some Hi-8 cameras are still functional) with a video stabilization system and should have a shutter speed of at least 1/2000 (digital) or 1/4000 (analog).¹⁴ Most consumer-grade cameras film at 30 frames per second (fps). Therefore some video loss is apparent compared with more sophisticated (200 fps) and expensive systems. Digital and Hi-8 video create less video noise and provide a superior viewing experience. For rapid viewing the recorded tape can be placed into a digital videocassette recorder that has a jog-shuttle device for stop frame viewing or frame grabbing. Alternatively, video editing tape decks, which are more expensive than traditional videocassette recorders, can be used. Digital images also can be reviewed on a computer and thus more accurately analyzed and edited. Turnkey systems including hardware and software using universal serial bus or IEEE 1394 rapid transfer technology are available.

Using video technology allows the clinician to critically examine the baseline lameness and lameness after diagnostic analgesia, record them in real time, analyze the differences in real time slow motion, maintain a permanent record for follow-up examinations, and demonstrate to the owner or trainer the difference in gait before and after a successful block. Video analysis also can be useful in demonstrating initial footfall, footfall after trimming or shoeing, and the effects of different types and weights of shoes. The technology gives one a new appreciation for lameness, motion, conformation, and gait at a walk, trot, or higher speed. The camera is much more sensitive than the human eye and can answer many questions and create new ones.^{12,15,16}

PREPARATION OF THE HORSE AND SAFETY CONSIDERATIONS

It is important that a horse be reasonably fit to perform an accurate treadmill lameness examination. STBs should be trained down to at least a 2-minute mile. Endurance horses, in which lameness may not occur for several miles, need

to be at least fit enough to accomplish this task easily. Other horses should be in regular work. To do otherwise places the horse and examination at risk. Unfit horses run the risk of exertional myopathy, thus obfuscating the results of any lameness examination.

We prefer horses to wear shoes when being examined for lameness. Tremendous friction and therefore heat are generated by the contact of the horse's foot and the treadmill belt. Whenever a foot contacts the belt, the foot slips and therefore causes friction. Many research horses that exercise daily on a high-speed treadmill have chronic foot problems secondary to the heat generated. This heat can be enough to melt the glue-on shoes at higher speeds. If the horse is not shod, the toes of the hind feet can break off and bleed, leading to substantial lameness for several weeks. We do not place any type of tape on the horses' shoes. We recommend using flat shoes, with no toe grabs, stickers, borium, or turndowns. This minimizes wear to the treadmill belt, which when used daily lasts 9 to 12 months before replacement is required. We recommend that shoeing changes be made 3 to 5 days before a treadmill examination, in case foot problems related to shoeing are found that may mask the horse's actual primary lameness.

Examination for lameness on a treadmill requires at least three people. One person controls the treadmill and the horse's head, one person stands behind the horse to keep it moving forward if necessary, and one person is the clinician. The clinician is responsible for operating the video equipment and observing the horse at a walk, trot, and any other desired gait. Occasionally, two people are required at the head for fractious horses.

Schooling of the average horse usually takes about 30 minutes to 1 hour before the horse is ready to be examined for lameness. Most (>99%) horses can be schooled and examined for lameness or poor performance in the same day. This period includes acclimating the horse to the treadmill and the fan noise, standing on the treadmill with the machine off, and moving with the treadmill at the walk, the trot, or pace at medium speed, a canter at low speed (7 m/sec) for non-STBs, and then at rest. STBs then are harnessed and moved up to a speed of about 7 m/sec for 200 to 300 m. Most horses adapt easily using this method of schooling, which is safe and successful in 99% of horses examined for lameness or poor performance. Occasionally, horses are recalcitrant or scared and need to be reschooled a day later and usually adapt well. Some horses (<1%) cannot be examined because the examination would not be safe for the horses or personnel.¹⁷

Safety of horses and personnel is paramount. Personnel must be cautioned to be alert at all times and not to stand behind the horse when the treadmill is moving. Shoes and horses can come off the treadmill without warning. Substantial injuries (e.g., tendonitis) occur in less than 1.5% of horses. Lacerations, broken-up hind feet, and myositis occur in less than 5% of horses.¹⁷ All horses wear protective boots on all limbs. All STBs are schooled first without equipment (tack), but with protective boots, and then they wear the normal equipment plus protective boots if they move at speeds greater than 7 m/sec.

To minimize the risk of injury to personnel and horses, it is important to have a trained team to examine each horse. Personnel should block any windows through which the horse can see out, eliminate as many noise distractions

as possible, and ensure that no doors can be opened in front of the horse during schooling or exercise. This allows the horse to concentrate on keeping up with the treadmill and minimizes fright or distraction of the horse during the examination.

LAMENESS DIAGNOSIS

Most lameness is seen best in all breeds with a minimum of equipment in place. STBs, which usually race checked up, are examined first with a minimum of equipment (i.e., no hobbles) and not checked up. Many lameness conditions in STBs can be obfuscated, changed, or eliminated when a horse wears its equipment and in particular, when checked up. Other horses are examined wearing just a halter unless some equipment change exacerbates the lameness (rare). A riding horse may need to wear side reins. Occasionally, STBs with carpal or stifle lameness are worse when wearing hobbles.

Horses are first examined at the walk and then at the trot and are recorded on video. Recording from the side is useful to evaluate stride length and frequency. Examination from the rear is helpful in evaluating the swing of the forelimbs and hindlimbs and the footfall.

Observation of lameness using a treadmill is different from the standard lameness examination because the horse is stationary relative to the observer, allowing viewing and video recording of the horse's gait from the side, front, and rear. The most useful gaits for observing lameness are the trot and pace. These are symmetrical gaits and allow for easier evaluation of lameness and gait rhythm.¹³

The horse should become comfortable at the trot, so that the lameness or gait abnormality can be established. An audible rhythmic pattern to the gait also becomes apparent. The horse is in rhythm (normal) or out of rhythm (lame). In addition to video recording for later viewing, it is important to evaluate the lameness concurrently to establish a baseline. If lameness is not readily apparent, reviewing the video immediately before performing diagnostic analgesia may be advantageous. Although detecting a difference in footfall is a standard part of any lameness examination, in our experience footfall may be exacerbated on a treadmill. Sound horses that trot have a symmetrical, diagonal, two-beat gait, and pacers have a symmetrical, lateral two-beat gait. The horse should be observed carefully for a change in how the horse swings its forelimbs or hindlimbs. In STB pacers, any change in how the horse moves from side to side at the poll or hips, when viewed from the rear after diagnostic analgesia, is important. These horses, whether pacing free-legged (no harness) or when in harness or checked up, have a tendency to swing from side to side and land more heavily or with greater excursion on the sound side. An in-depth description of these gaits is available.¹³

In addition to elimination of lameness, a change in stride characteristics may occur, including stride frequency, length, and swing plane. Some horses not accustomed to the treadmill, or not comfortable on the treadmill, may have an increased stride frequency and shortened stride length, which also may be seen in lame horses.¹³ Once accustomed to the treadmill, many sound horses exercised at medium to higher speeds on a treadmill have a longer stride and thus a lower stride frequency.¹⁸ However, lame horses may have an increased stride frequency and

shortened stride length.¹⁹ This can best be demonstrated and seen using video.

Other, more subtle changes include improvement in gait fluidity, improvement in use of the head and neck and shoulder, and change of an anxious eye expression, flexion of major joints, foot flight, width and rhythm of gait, and footfall. Occasionally, horses may become stiff or anxious and lame or lamer in front or behind during or after exercise. Exercise should be discontinued. Exertional myopathy (see Chapter 83) or aortoiliac thrombosis (see Chapter 50) should be considered likely causes.^{20,21}

ADDITIONAL TESTS

It is useful to measure creatine kinase and aspartate transaminase concentrations before and after exercise to monitor

horses for subclinical myopathy, overt myopathy, or previous undiagnosed myopathy.²¹ If aortoiliac thrombosis is suspected, a rectal examination and an ultrasonographic examination per rectum should be performed. Horses with aortoiliac thrombosis commonly become lame behind during or shortly after commencement of exercise.²⁰ They have an anxious look and can sweat more profusely than their level of exercise would dictate.

The treadmill provides a smooth, even surface at a constant, controllable speed and a horse that is stationary relative to the observer. Some horses are lame in hand, but not on a treadmill, and some are lame on a treadmill, but not in hand. Horses that are lame only on turns are difficult to evaluate on a treadmill, which operates only in a straight line. Some horses will not tolerate working on a treadmill.²²⁻²⁴

SECTION 2

The Racehorse

Chapter 99

The Sales Yearling

▣ PURCHASE EXAMINATION OF A THOROUGHBRED SALES YEARLING IN NORTH AMERICA

*Benson B. Martin Jr., John C. Kimmel,
and Mark W. Cheney*

Veterinary inspection of a Thoroughbred (TB) yearling at public auction requires expertise and experience.¹⁻¹³ Previously, yearlings commonly were examined after purchase, and if a problem was discovered subsequently, a lengthy, expensive, and frequently unsatisfactory arbitration for buyer and seller alike was implemented. Recently a shift has occurred toward a comprehensive examination of yearlings before purchase.

It is important that the veterinarian's role be defined in advance with all the necessary parties, such as the potential trainer, owner, and syndicate manager. Clinicians should determine whether they are prepared to offer advice concerning the pedigree or whether their advice will be strictly veterinary. It should be made clear that no guarantees of future performance can be given. Any potential conflicts of interest must be declared, including whether the veterinarian is involved as an agent, breeder, purchaser, or consignor.

Veterinarians should establish precisely for whom they are working and to whom information can be divulged. They should not give privileged, confidential information to anyone else. Provide a representative estimate of the fee for the examination. Sometimes a buyer may wish to gain

access to information obtained by another. This is acceptable provided that the original client gives permission. In this way the fee may be split between two or more prospective purchasers. If clinicians work regularly with purchasers, they may be able to contribute to their buying policy, which may include consideration of pedigree information, budget, conformation type, sex, and potential resale breeding value. Excellent communication with trainers is important, because they ultimately have most control of the horse when it enters training.

It is also important to establish a good relationship with the consignor or agent. Veterinarians should be courteous and respectful, should arrange a mutually suitable time to examine the yearling, and should request permission before carrying out endoscopic or radiographic examinations.

Experience is essential to make accurate interpretations of conformational or gait abnormalities, radiological or endoscopic findings, and the results of examination of the eyes and heart. Knowledge of pedigrees also can be helpful.

CONDITIONS OF SALE

It is important to be aware of the conditions of sale for each sales company. These conditions usually differ with the age of the horse, use of the horse, and sales company. Sales are weighted in favor of the consignors and conducted with an attitude of caveat emptor. The warranty is limited, with no implied warranty for use or soundness other than those conditions published in the sales catalog. The repository is an area at the sale location set up for viewing radiographs, and videotapes of the upper airway at rest, in selected horses. If veterinarians determine this information is not adequate or satisfactory, it is their responsibility to obtain the desired information. They should examine all available information carefully. If any problem is discovered after the sale that was evident in

the repository information, the consignor is not liable. The sales company makes no warranty about the accuracy or completeness of repository information and makes no interpretation of it. Repository information is for the convenience of potential buyers and as a courtesy of the consignors and also decreases the exposure of yearlings to repetitive and stressful examinations. Other information, such as previous surgery, medical problems, eye problems, current medication, vaccination status, Coggins and equine viral arteritis status, and availability of radiographs, may be available from the consignor, if the veterinarian asks.

PRESALE OR POSTSALE EXAMINATION

Currently many persons prefer presale inspection. This eliminates the process of arbitration, places the onus of disclosure on the consignor, and makes the buyer responsible for obtaining all available information before sale. If the buyer does not obtain such information (such as identification of a chip fracture), the buyer has no recourse. With examination after sale the only problems for which a horse may be returned are listed in the catalog as conditions of sale. The veterinarian is responsible for knowing these conditions and the terms under which arbitration can occur. Arbitration usually must be implemented within 24 hours after the sale of the yearling, and the yearling must still be on the sale grounds. Failure to comply with this negates any chance of arbitration.¹⁴ Arbitration usually involves three veterinarians representing the sales company, the consignor, and the buyer respectively.

CLINICAL EXAMINATION

A yearling TB is immature, and its physical appearance may change considerably. Developing the skills to predict how each horse may develop by learning from experienced persons is worthwhile. Assess the general attitude of the horse, its eye, and its presence. Be aware that many yearlings are tranquilized for ease of inspection, so one may not get a true picture of the horse's attitude, which can be important in training and racing. Evaluate the horse's conformation (see Chapter 4). Look at the horse's feet, because the old adage "no foot, no horse" is true. Assess the horse's shoulder, hip, top line, and length of back and then the lower limbs. A good shoulder and hip can accommodate many conformational defects lower in the limb. In our opinion the following conformational abnormalities may predispose to lameness and should be avoided: back at the knee, tied in behind the knee, offset knees, and exceptionally straight hindlimbs. Carefully evaluate the shoeing and trimming of the feet, because good farriers can make a horse that toes in or out appear to be almost normal, and they are very adept at repairing an abnormal hoof appearance. After examining the horse walking in hand, perform a more detailed examination in the stall, out of sight of the general public, as a courtesy to the consignor. Assess carefully any swellings, and palpate the joints, tendons, and ligaments. Examine the eyes and auscultate the heart. Look for evidence of previous periosteal stripping or other surgery, evident as dermal thickening or white hair in areas where surgery is commonly performed.

ENDOSCOPY, ECHOCARDIOGRAPHY, AND OPHTHALMOLOGY

The veterinarian should ask the consignor or his manager for his assistance and permission to perform an endoscopic, radiographic, and echocardiographic examination of the horse, and should arrange a time to do so. A resting endoscopic examination of the horse's upper airway should include stimulating the horse to swallow and holding off the horse's airway. This allows more complete evaluation of the horse's upper airway function at rest. Echocardiographic examination is not performed routinely but can be used to assess heart size and left ventricular free-wall contractility or to detect abnormalities.¹⁵ A brief eye examination should be conducted, looking carefully, in particular, for corneal scars.

RADIOGRAPHY AND RADIOLOGY

For many yearlings, radiographs are obtained up to 30 days before the sale and are stored in the repository at the sale. Most states allow only veterinarians licensed in the state to examine these radiographs. The examining veterinarian is responsible for ensuring that all the desired images are present, that the radiographs are properly identified, and that they are of suitable quality. The radiographs should be interpreted carefully. If the radiographs are incomplete, of poor quality, or absent completely, the veterinarian should arrange to have his or her own complete set of radiographs obtained. In our opinion a comprehensive examination consists of 46 images, plus any additional images needed on the basis of clinical examination. These images include the following:

- Front feet: lateromedial (LM) and dorsopalmar (DPa)
- Front fetlocks: DPa, LM, flexed LM, dorsolateral-palmaromedial oblique (DL-PaMO), and dorsomedial-palmarolateral oblique (DM-PaLO)
- Carpi: DPa, LM, flexed LM, DL-PaMO and DM-PaLO
- Hind fetlocks: dorsoplantar (DPI), LM, dorsolateral-plantaromedial oblique (DL-PIMO), and dorsomedial-plantarolateral oblique (DM-PILO)
- Tarsi: DPI, LM, DL-PIMO, DM-PILO
- Stifles: caudocranial, LM, and caudolateral-cranio-medial oblique (CdL-CrMO)

However, the following 36 images are those required by the Keeneland sales repository in 2009:

- Front fetlocks: dorsal 15° proximal-palmarodistal oblique, LM, flexed LM, DL-PaMO, and DM-PaLO
- Hind fetlocks: dorsal 15° proximal-plantarodistal oblique, LM, flexed LM, DL-PIMO, and DM-PILO
- Carpi: flexed LM, DL-PaMO, and DM-PaLO
- Tarsi: D10°L-PIMO, LM, and DM-PILO
- Stifles: LM and Cd20°L-CrMO including the medial condyle of the femur in its entirety

This provides a comprehensive, but not all-inclusive, picture of the horse's musculoskeletal system. Other sales companies may have different requirements. The veterinarian is responsible for ascertaining the requirements.

A number of common radiological findings may eliminate a horse from further consideration.¹⁶ Fractures of the

carpus, distal phalanx, tarsus, proximal sesamoid bones, and the second or fourth metacarpal (metatarsal) bones generally are considered unacceptable, whereas small osteochondral fragments on the dorsal aspect of a fetlock joint may be acceptable. Osteoarthritis (OA) of the carpus, fetlock, or proximal interphalangeal joint is not acceptable. However, small osteophytes on the dorsoproximal aspect of the third metatarsal bone (MtIII) do not necessarily preclude a successful athletic career.

The relevance of osteochondrosis depends on the location of the lesion, its size and severity, the presence or absence of OA, and the prognosis for racing after surgical treatment. A yearling with a small fragment may be amenable to surgical treatment and should be discussed with the buyer. If a fragment has been removed previously and no evidence of OA exists, the horse may be a reasonable risk for purchase. Horses with osteochondral fragmentation of the cranial aspect of the intermediate ridge of the tibia or small lesions of the lateral trochlear ridge of the femur usually are treated successfully by surgical removal. Horses with osteochondral fragments on the proximo-plantar aspect of the proximal phalanx in the hindlimbs (which may actually be traumatic in origin) represent a reasonable risk.

If an osseous cystlike lesion is identified, especially one involving the stifle or fetlock, the horse generally should be considered at high risk for developing lameness. Other radiological abnormalities that may preclude purchase include sesamoiditis, laminitis, and active splints.

Few objective studies detailing the relevance of radiological changes and race performance are available for review. In a study to determine prevalence of radiological changes in the repository radiographs of 1162 TB yearlings selling in Kentucky, fragmentation of the dorsal proximal aspect of the proximal phalanx in the forelimb (1.6%) was more common than that of the palmar aspect (0.5%), whereas in the hindlimb fragmentation of the proximal plantar aspect of the proximal phalanx (5.9%) was more common than that of the dorsal aspect (3.3%).⁵ Radiolucent defects, bony fragments, and loose osseous fragments of the distal aspect of the third metacarpal bone (McIII, 2.8%) and the MtIII (3.2%) were found, and most yearlings (98%) had radiologically apparent vascular channels of the proximal sesamoid bones. Irregular channels (>2 mm wide or with nonparallel sides) were more common (79%) than were regular vascular channels (56%). The cranial aspect of the intermediate ridge of the tibia (4.4%) was the most common site of osteochondral fragmentation in the tarsus.⁵ The authors concluded that although some radiological changes were common, others such as fragmentation and radiolucent defects were uncommon, and if rare, the effect of radiological changes on race performance would be difficult to study.⁵ In a second study race performance of these yearlings was evaluated, and overall 81% started a race as a 2- or 3-year-old.⁶ Fourteen of 24 horses (58%) with moderate or severe palmar supracondylar lysis of the McIII, 8 of 14 (57%) of those with enthesophyte formation of the proximal sesamoid bones, and 19 of 30 (63%) with radiological changes of the dorsomedial aspect of the middle carpal joint started a race.⁶ The odds of starting a race with these three radiological changes were three times lower than the overall population, a result that was statistically significant.⁶ Twenty-five of 36 (69%) of yearlings with

fragmentation of the dorsoproximal aspect of the proximal phalanx in a hindlimb raced, a percentage that was lower than in the overall population but not statistically significant.⁶ Yearlings with enthesophyte formation of the proximal sesamoid bones in the hindlimbs placed in a significantly smaller percentage of starts and earned significantly less money per start.⁶

DRUG SCREENING FOR ANABOLIC STEROIDS AND OTHER PROHIBITED PRACTICES

In 2008, Keeneland instituted a policy stating that "a limited warranty provides that any yearling entered at the Keeneland Fall Yearling Sale shall not have been administered any exogenous anabolic steroids within 45 days of the date of the sale." A prospective purchaser may have the horse tested for the presence of exogenous anabolic steroids. If the blood is found to be positive, the buyer has the right to rescind the sale and return the horse to the seller.

The following practices are prohibited once a horse has entered the sale ground:

1. Extracorporeal shock wave therapy
2. Acupuncture and/or electrostimulation with the intent of altering laryngeal function
3. Internal blister (behind the carpus) to alter conformation

■ PURCHASE EXAMINATION OF A THOROUGHBRED SALES YEARLING IN EUROPE

David R. Ellis

Yearling sales occur in Europe later in the year than in the United States. The earliest, at Deauville in Normandy, is in early August, but in England and Ireland the main sales are conducted from the end of September to early December.

MONITORING AND SALE SELECTION

Most higher-class farms that offer yearlings regularly monitor the growth rates, weights, and conformation of the young stock. Such monitoring often is done with veterinary help and is conducted in close cooperation with the farrier. This should ensure that any corrective farriery is undertaken as early as possible, thus gaining maximum benefit and not leaving correction until too late in the growth of the animal. The second growth spurt, from 9 to 12 months of age, is an important window of opportunity in which to make substantial changes through corrective techniques. Regular veterinary inspections also help to detect disease, such as acquired deformities or developmental orthopedic disease, early enough to allow successful remedial measures to be undertaken. As in the United States, selection of the sale at which the yearling is to be offered is made in the spring, usually April. A few consignors conduct radiological surveys at this time to help with this selection and to deal with potential problems such as bone chips and osteochondrosis.

PREPARATION

Yearlings are brought in from pasture 6 to 8 weeks before sale for increasingly intensive preparation. This involves walking exercise with the horse led by hand, sometimes using uphill work, or using a walker. Treadmills were once used commonly, but they have fallen from favor because they tend to give a horse a goose-stepping type of action. Lunging is introduced later in preparation, particularly for the heavier or fatter yearlings, and this will be short and at a sharp trot and canter, on both reins and often twice daily. Lunging is more important to sale preparation in Europe because most yearlings, particularly the more expensive, will undergo respiratory examination at the canter by the purchaser's veterinary surgeon immediately after sale. Education and fitness are important if this post-sale test is to be conducted safely and satisfactorily. A substantial risk of injury exists during lunging if the exercise is not conducted carefully and on a suitable surface. Interference injuries, such as brushing or overreach wounds, can be prevented by using protective boots, farriery, and careful buildup of speed and fitness and particularly by using a sympathetic surface. Surfaces such as deep sand or dry wood chips may become too deep or slide away under the horse. Paddock turf can be too firm and slippery to be safe. Modern surfaces, such as Fibresand (Fibresand UK, Mansfield Sand, Nottinghamshire, United Kingdom) or Polytrack (Martin Collins Enterprises, Hungerford, United Kingdom) on a slight camber are safer. Some of the more successful vendors place more emphasis on lunging to achieve fitness and muscle condition than on walking. Excessive walking usually makes the person leading the yearling fitter and leaves the yearling bored and slovenly.

Yearlings usually come up from summer grazing in good, perhaps heavy, body condition. Converting the fat yearling into a well-muscled potential athlete by judicious feeding and exercise is an art. Overfeeding the leaner yearling may lead to physitis (see Chapter 57). As the weather starts to cool, most yearlings will be rugged (blanket applied) in the stable to ensure that they do not start changing to a winter coat. This change in management means that less energy is required in the diet.

Using medication to promote growth or body condition is much less common nowadays, partly because certain vendors became renowned for these practices and suffered in the long term. Anabolic steroids are not licensed for use in the horse, now deemed in mainland Europe to be a food animal. Several years ago Tattersalls, the important Bloodstock Auctioneers, conducted a pilot program of drug testing yearlings for steroids at their premier sale to assess for steroid use. Although the results were never published, the effect of this exercise was salutary.

During the preparation period, front shoes will be fitted, and some changes can be made to hoof trimming and balance to conceal slighter conformation faults, fill horn defects, and ensure that hoof wear during exercise is not excessive. Few yearlings will be fitted with hind shoes. It is important that the final shoeing not be too close to the sale date, so that tight nails or other shoeing problems do not cause lameness.

Orthopedic problems encountered in the yearling year can include physitis—mainly at the distal radial physis,

but occasionally also the distal tibial physis—splints, sesamoiditis and strain of suspensory ligament branches, osteochondrosis, or bone cysts or osseous cystlike lesions. Horses with bone cysts often have clinical lameness when forced exercise commences, as in sale preparation, or breaking in immediately after sale. Managing orthopedic problems in the months before the sale not only requires the ideal veterinary measures according to the disease, but also requires giving consideration to the importance that potential purchasers place on the problem (little perhaps in yearlings with small settled splints) and to alternative strategy if the chosen sale has to be missed. If, for example, a yearling develops a bog spavin that requires surgical removal of osteochondral fragments 3 months before sale, having the joint back to normal, the clipped hair regrown, and the yearling adequately fit to offer for auction would be a close race to run. The ethics of offering such a yearling also have to be considered.

CONDITIONS OF SALE

Conditions of sale for yearlings at the main European auction houses do not include orthopedic conditions or surgery, with the exception of denervating at Doncaster (United Kingdom) and Goffs (Ireland). The latter auction house also deems wobblers to be returnable. Purchaser power and the example from the United States have introduced more presale radiographic examinations at premier sales. These now mostly are conducted by the vendor, and films of standard images of the carpi, the hocks, all fetlocks, and the stifle joints are available for examination by purchasers' veterinary surgeons. No official repository exists, but viewing facilities are available at the sale paddocks.

Radiographs are not essential to a profitable sale, because some of the most successful vendors at Tattersalls have not allowed presale radiography or endoscopy. They stand by their yearling on orthopedic matters and rely on the auctioneer's condition of sale regarding wind conditions. The latter is more stringent than in the United States regarding laryngeal hemiplegia but does not include other upper respiratory disorders that are considered intermittent, treatable, or so rare (e.g., rostral displacement of the palatine arch has been detected three times in 17 years) as to be dealt with on a single-case basis. Conditions of sale for English and Irish yearlings state that a horse is returnable if it is found to make a characteristic abnormal inspiratory sound when actively exercised (a roar or whistle at the canter) and to have endoscopic evidence of laryngeal hemiplegia that was not declared before sale. Horses are lunged for this examination soon after sale and before they leave the sale paddocks.

ORTHOPEDIC CONDITIONS

The most commonly found orthopedic condition to cause difficulty after sale is a subchondral bone cyst in the medial femoral condyle (see Chapter 46). Characteristically, lameness occurs soon after the horse starts lunging exercise for breaking in. Clinicians experienced with yearlings always obtain radiographs of a yearling's stifles if lameness develops in a hindlimb under these circumstances, with no obvious clinical sign of origin of pain. Vendors usually are approached with a view to taking the horse back, particularly if the money has not changed hands, but not all will

Fig. 99-1 • Dorsolateral-palmaromedial oblique radiographic image of a metacarpophalangeal joint. Irregularity and enthesophyte formation on the abaxial margin of the lateral proximal sesamoid bone reflect sesamoiditis. (Courtesy I.M. Wright, Newmarket, England.)

do so. No case has yet come to court, and it must be admitted that after conservative or surgical treatment some such horses have gone on to race satisfactorily, but not as 2-year-olds.

Conditions commonly found during prepurchase veterinary examination include the following:

- Enlargement of the proximal sesamoid bones can be the most important condition, because enlargement may result from fractures sustained as a young foal that have healed by fibrous union (see Chapter 36). Enlargement is often multiple and can involve the apex or the base of the bone. Sesamoiditis, with or without suspensory branch desmitis, also is seen in yearlings (Figure 99-1).
- Any effusion of a joint must be viewed with suspicion, particularly if forced flexion is painful. Purchase cannot be recommended, and even if good-quality radiographs reveal no abnormality, a guarded opinion is given.
- Asymmetry of front feet is common, and a slightly narrow hoof need not detract, providing the hoof is not twisted or shear heeled. Feet are sometimes overcorrected, which leaves them unlevel when viewed from the front standing on a hard, level surface or when the foot is held up and the solar surface is inspected. These conditions can cause orthopedic problems in training, and only mild imbalances are acceptable. A narrow, boxy foot is probably a lesser evil than a broad, flat foot with a collapsed heel.
- Lameness rarely is seen at sale examinations, but it can be difficult to spot because routine examination involves only inspection at the walk. Trotting can confirm or deny lameness. Ataxia can be difficult to discern because the frequently inspected yearling tires during the day and can appear weak. Also, some yearlings are given mild sedatives to control behavior, which may give a similar effect.
- Presale injuries are common. Yearlings travel by road or ferry, and knocks and abrasions often cause more distress to the vendor than the yearling. Capped hocks are particularly common but rarely important.

ULTRASONOGRAPHIC EXAMINATIONS

Ultrasonographic examinations have been introduced by some purchasers. Ultrasonography has been used mainly to measure dimensions of the cardiac chambers, but some horses that have had injuries or other soft tissue anomalies may be offered with ultrasonographic images provided by the vendor or, with the vendor's permission, may be examined by ultrasonography by a purchaser's veterinarian. Conditions that may warrant such an examination to give purchasers confidence include thickening of suspensory ligament branches or fleshy superficial digital flexor tendons (SDFTs). The former is seen distally where the suspensory ligament branch attaches to the proximal sesamoid bone and usually results from a mild strain. Whatever the fiber pattern appearance in these horses, they often need considerable patience in training as 2-year-olds but ultimately can stand racing. Fleshy tendons are a thickening or bowing of the SDFT in the forelimbs that is seen in yearlings or 2-year-olds in training. They show minimal or no soreness on digital pressure and on ultrasonographic examination have an increased cross-sectional area of the middle third of the tendon and a coarseness of fiber pattern, but no core lesion or accumulation of fluid (Figure 99-2). These horses do well if they are shown patience in training (horses with mild lesions are capable of light cantering exercise but not galloping) and are not given aggressive veterinary treatment. With regular monitoring the tendon(s) usually thins and straightens to normal during the summer months, and many horses can be raced as 2-year-olds. This condition is probably an adaptive mild inflammation, because it occurs in yearlings that have had no managed exercise and in 2-year-olds in early training. Fleshy tendons should not be considered in the same serious manner that a strain or core lesion would demand in an older horse and pose only a slightly greater risk of tendonitis later in the racing career. Local antiinflammatory medication or counterirritation is sometimes applied, but the efficacy is dubious.

■ NORTH AMERICAN STANDARDBRED SALES YEARLING

Mike W. Ross

Veterinary inspection of the Standardbred (STB) sales yearling at the major sales is limited compared with that of the North American TB yearling. At most sales the number of veterinarians inspecting horses for their own potential purchase is similar to the number of those hired by owners and trainers to provide opinions.

LOCATION AND TIME OF MAJOR SALES

The major sales take place in the fall in Kentucky and Pennsylvania, with smaller sales elsewhere. Small consignors may sell directly through the sales company, but large breeding farms or well-known agents sell most STB sales yearlings. Separate dispersal sales of broodmares, sucklings, and weanlings occur with the yearling sales or at a later date. Horses of racing age sell at various sales across North America, but no specific sales occur for 2-year-old horses in training.

Fig. 99-2 • **A**, Transverse (on the left) and longitudinal ultrasonographic images of the midmetacarpal region of a 2-year-old Thoroughbred with fleshy tendons. Subcutaneous edema and enlargement of the superficial flexor tendon are present. **B**, Enlarged transverse image of horse shown in **A**. The entire cross-sectional area of the tendon has a diffuse reduction in echogenicity.

CONDITIONS OF SALE

All STB sales yearlings sell as is, meaning that when the hammer falls, the buyer owns the yearling in the condition in which it was sold and must pay according to the conditions of sale. The sales companies are not responsible for determining the suitability of the horse for racing or for unsoundness discovered after the sale. The sales company announces the yearling's sex and reproductive changes or abnormalities (gelding, spayed, ridgeling, cryptorchid), if the yearling was conceived by embryo transfer, and if the horse has been "nerved." Consignors sign a contract with the sales company that includes details about remediation if a dispute regarding soundness occurs, but the legal responsibility is with the consignor, not the sales company. Arbitration, according to the laws of the state in which the yearling was sold, is used if a suitable arrangement cannot be made.

Consignors, usually large farms acting as agents or independent sales agents, have a separate contract with individual owners to represent them at a sale. Owners are required to give information about neurological status, cribbing, fractures, neurectomy, or unsoundness of sight or wind at least 30 days before sale. The consignor determines if information regarding these conditions is announced at the sale, but no contract stipulates that known conditions, such as lameness or previous surgery, be announced at the sale. To prevent disputes and to preserve their integrity, consignors may request that surgical procedures, such as arthroscopy to remove osteochondritis dissecans (OCD) fragments, or other pertinent information be announced. Verbal announcements and the availability of presale radiographs and surgical reports may be detrimental to the sale

price, despite resolution of the condition, although removal of tarsocrural OCD fragments is usually acceptable. Philosophical differences exist among consignors, and only some provide presale information. Thus little incentive exists to disclose information or to investigate problems before sale. Many owners prefer that problems not be investigated so that the yearling may be consigned without disclosure.

RESOLUTION OF DISPUTES

The consignor is primarily responsible for adjudicating conflicts about STB sales yearlings. Because sales companies stipulate yearlings are sold as is and arbitration is the final remedy for disputes, consignors often are forced to provide flexible remediation when disputes arise. If consignors are owners, they deal with problems directly with buyers. If consignors are agents for owners, they become the intermediary. In most instances consignor and buyer attempt to avoid arbitration. Problems arise when a condition is found after the sale, usually on postsale radiographs, that is judged to be detrimental to the yearling's future potential as a racehorse. The buyer refuses to pay and contacts the consignor. Influential large buyers can often stand their ground, and the consignors may refund money, give credit to the buyer for the future purchase of a yearling, pay for surgery if necessary, or lower the sale price. If agreement cannot be reached, arbitration ensues. The high prevalence of OCD fragments means that most disputes concerning these are judged in favor of the consignor. Disputes regarding carpal chip or other fractures, osseous cystlike lesions, extensive radiolucency of the proximal sesamoid bones, or unusual OCD or traumatic conditions often are resolved in

favor of the buyer. Fractures are considered important, and the term should be avoided if a condition is known by most to be a manifestation of OCD. Failure to disclose a condition is most difficult to prove but often is suspected by disgruntled owners.

ROLE OF THE VETERINARIAN

Because repository radiographs are not available, the veterinary presence at major sales is minimal. Veterinarians are sometimes asked to accompany buyers to farms before sale, or to the sale itself, but are handicapped by not having the ability to review radiographs. Influential buyers may be able to convince consignors to allow radiographic and endoscopic examinations and may otherwise threaten not to bid on horses. Veterinarians often are asked to judge conformation and interpret what effect abnormalities may have on future race performance. They may be asked to review pedigrees, but in general, trainers and owners are extremely knowledgeable. Veterinarians are usually prohibited from performing radiographic and endoscopic examinations at a sale or, if they are allowed to do so, must perform the examinations after normal sale hours. However, these examinations usually are allowed for horses of racing age.

CONFORMATION

A definite relationship between conformation and the development of certain lameness conditions exists in the STB sales yearling (see Chapter 108). A difference in the relevance of abnormal conformation exists between a trotter and pacer. Sickie-hocked conformation is acceptable in a pacer, unless severe, but in a trotter this conformation leads to lameness. A sickie-hocked trotter is usually fast but lame. Mild sickie-hocked conformation is considered by some to be desirable in a pacer, but in horses of either gait, this abnormality predisposes to curb, osteoarthritis of the distal hock joints, and fracture of the central or third tarsal bones (see Chapters 44 and 78). In-at-the-hock conformation is undesirable in a trotter and a pacer. Calf-knee or back-at-the-knee conformation is prevalent in STB yearlings, and if mild and in a pacer the conformation is acceptable, but in a trotter this abnormality should be avoided. Any conformational abnormality of the carpus in a trotter should be considered carefully. Bench-knee or offset-knee conformation is undesirable in a trotter or pacer (see Chapter 38). Tied-in below the knee leads to superficial digital flexor tendonitis, especially in a pacer (see Chapter 69). I believe TB racehorses can tolerate clubfoot conformation better than STBs, and this abnormality should be avoided. Metacarpal and metatarsal exostoses are common, but usually of little concern, unless large or proximally located near the carpus or tarsus, respectively.

Videotapes of yearlings in action (loose exercise in paddocks or jogging on the track) are usually available and are thought to be much more informative in trotters than in pacers. Desirable characteristics of trotters include a wide gait behind and a narrow gait in front. An acceptable trotter can be base narrow and toed out in front, because hindlimbs often land lateral to the forelimbs (called *passing gaited*), and interference injury is minimal. Base-narrow, toed-out conformation predisposes a pacer to considerable interference injury. In pacers, base-wide forelimb conformation

is acceptable, whereas in a trotter this predisposes to interference. Toed-in conformation, if mild, is acceptable in a pacer but not in a trotter, because interference injury and lateral branch suspensory desmitis are problems.

RADIOGRAPHY AND RADIOLOGY

Because no repository for radiographs is provided and many consignors actively discourage presale radiography, radiographs are usually unavailable. However, some farms examine all STB sales yearlings radiologically before the sale, remove OCD fragments, and have radiographs available on request. Because OCD fragments of the tarsocrural joint generally cause effusion in late weanlings and early yearlings, these often are removed surgically before sale, but this may not be announced. Radiographs may be available for other types of injuries, such as lumps or bumps in the metacarpal or metatarsal region or elsewhere, to demonstrate that the injury is unlikely to affect future race performance.

Radiographs commonly are obtained after sale and may lead to questions about future soundness and, in some horses, arbitration. In general, radiological changes that affect racing performance are radiolucent defects of the proximal sesamoid bones (sesamoiditis and osseous cyst-like lesions), large conglomerate OCD fragments involving the plantar processes of the proximal phalanges (intraarticular and extraarticular fragments) in trotters, osseous cystlike lesions of the distal aspect of the proximal phalanx and middle and distal phalanges, large OCD lesions of the lateral trochlear ridge of the femur and subchondral bone cysts in the medial femoral condyle, single or multiple fragments located in the distal sesamoidean ligaments (rare form of fragmentation seen in the forelimb, thought to be a manifestation of OCD), carpal chip fractures, and various forms of osteoarthritis. The mere presence of OCD fragments does not necessarily affect sale price if the condition is known before the sale, and certainly in most yearlings does not preclude future soundness and successful racing. The most common sites of OCD involve the tarsocrural joint and the metatarsophalangeal and metacarpophalangeal joints. Once discovered, these fragments are often removed prophylactically before training begins. Management of STBs with fragments in the metatarsophalangeal joint is discussed elsewhere (see Chapter 42).

FUTURE DIRECTION

Many disputes occur between buyers and consignors concerning abnormalities in postsale radiographs, lameness, or neurological disease. Determination of when a lesion developed, if a true fracture exists, real or perceived effects on prognosis, and chain of custody (in whose care the yearling was when the problem was noticed) complicate final payment. These issues generally are resolved between the consignor and buyer (see the previous discussion), but occasionally arbitration is necessary and usually favors the consignor. Availability of presale radiographs in a repository would be preferable and a strong forward step for the STB industry, and although this change is not yet well accepted, mandatory radiographic examination is gaining support from some of the most influential owners and agents.

Pathophysiology and Clinical Diagnosis of Cortical and Subchondral Bone Injury

Elizabeth J. Davidson

PATHOPHYSIOLOGY

Bone is an amazing living tissue that is able to conform and adapt to its environment. When bone is exposed to a load, it deforms. This deformation is elastic and within certain limits; bone returns to its original state once the load is removed. If the degree of deformation is beyond bone's upper limit, complete failure occurs. Under other conditions, bone may be subject to loads that are persistently different. Alterations in bone strain patterns develop, and the bone responds accordingly. Bone will then counteract the variation in load by changing its inertial properties via the processes of modeling and remodeling. In time, bone will modify its shape and structure, effectively adapting to the load under which it is placed (Wolff's law).

The term *modeling* refers to the geometric sculpting of bone by formation or resorption.¹ With modeling, osteoblasts and osteoclasts work independently, resulting in increased or decreased bone density. Resorption occurs when strain patterns are below the minimum threshold, and bone formation occurs when bone strain is above the maximum strain threshold.¹ In cortical bone, modeling adaption results in periosteal thickening (bone formation) or thinning (bone resorption). In trabecular bone, subchondral sclerosis or osteoporosis ensues. Eventually, modeling alters the size, shape, and density of bone. *Remodeling* refers to the coordinated action of osteoclasts and osteoblasts resulting in the removal of biomechanically inferior bone and replacement with new bone.¹ Osteoclasts move through bone at a much quicker rate than osteoblasts; therefore bone resorption (within weeks) is followed by bone formation (months).

Bone modeling and remodeling are active ongoing processes and can occur in the same bone at the same time. These processes are driven by site-specific bone strain patterns, although the exact mechanism by which strain induces bone change is unknown. Throughout life, bone continually adapts to its physiological loads by modeling and/or remodeling until its mechanical stimulus is normalized. These processes ensure the mechanical integrity of the skeleton. For example, when a horse undergoes athletic training, its bones are exposed to increasing and varying loads at specific locations. In turn, bone responds by adding more bone to regions of higher load. An adaptive site-specific response to race training in Thoroughbred (TB)

horses is the dramatic thickening that occurs in the dorso-medial aspect of the third metacarpal bone (McIII).

In ideal situations, a balance exists between load and the rate of bone adaptation. Repetitive cyclic loading produces an accumulation of focal microdamage at sites that are maximally stressed. Microdamage incites a bone response, followed by successful repair and remodeling. If there is imbalance between removal and replacement, the very process of bone repair may contribute to a bone's failure. Because osteoclasts act more quickly than osteoblasts, transient weakness occurs after damaged bone has been removed and before completion of bone replacement. Prolonged or rapid increases in load, such as those during high-speed workouts and racing, result in an accumulation of microdamage. The resorptive phase of remodeling may then exceed replacement capacity and transiently weaken the bone.^{2,3} This focal weakness can function as a stress riser and allow initiation of a complete fracture or fragmentation under otherwise normal physiological loading.⁴

Failure of the bone to adapt in a timely fashion combined with continual and compounded microdamage results in stress-related bone injury.⁵ Horses undergoing race training and racing are particularly susceptible to injury because their bones are constantly subjected to large repetitive loads. Risk for injury is high until a satisfactory adaptive bone response is completed.³ Evaluation of post-mortem specimens indicates that most musculoskeletal injuries are overuse injuries. Evidence of stress remodeling has been observed in equine long bones (the McIII, humerus, scapula, or tibia), the third carpal bone (C3), the pelvis, and vertebrae.⁶⁻¹⁴ Site-specific pathology includes periosteal callus, sclerosis of endosteal or subchondral bone, and focal osteoporosis.

Stress-related cortical bone injury is commonly referred to as a *stress* or *fatigue fracture*. Stress fractures occur in horses undergoing intense exercise (repetitive high-strain loading) and are not correlated with a specific traumatic event.^{3,8,15-17} They are associated with activities that produce repetitive loading of the involved bone. Repeated cyclic loading of cortical bone results in loss of stiffness, reduction in strength, and development of microcracks. With continued loading, microcracks propagate and coalesce into macrocracks (i.e., stress fractures). Stress fractures are regularly identified, clinically and at postmortem examination, in consistent locations presumably at sites of maximal load. They are very common in racehorses and are a well-recognized cause of lameness. If the stress remodeling continues in an unbalanced fashion, trauma to an already fatigued bone can lead to catastrophic fracture. Periosteal callus, indicative of preexisting reparative response, at equine cortical fracture interfaces^{6,13} is common and provides evidence of a continuum of stress-related bone injury.

Like cortical bone, subchondral bone is susceptible to stress-related bone injury. Although features of bone modeling and remodeling are similarly induced, depending on the mechanical impact periosteal callus is not seen. Normally, the compliant subchondral plate acts as a shock absorber between articular cartilage and subchondral bone, thereby dissipating the impact to the articular surface. Repeated loading results in subchondral bone mineralization and subsequent stiffening to combat the increased

bone strain. The progressive increased bone density of the trabecular bone adjacent to the subchondral plate of the radial fossa of the C3 and the palmar condyles of the McIII or plantar condyles of the third metatarsal bone (MtIII) are examples of a subchondral response in race-trained horses.^{12,18,19} As with cortical bone, repetitive loading of the subchondral bone may result in a repair process dominated by the resorptive phase of remodeling. Associated focal subchondral osteoporosis and microcracks may result. Small cracks may develop into larger fractures, resulting in fragmentation and overt fracture along articular margins.²⁰ Preexisting subchondral sclerosis is commonly seen in racehorses with distal McIII condylar fractures²¹ and is a proposed precursor to C3 slab fractures.^{12,22} Sclerotic subchondral bone may result in articular cartilage damage. Progressive cartilaginous erosion and ulceration has been identified at areas of increased subchondral thickness.^{9,23,24} Collapse of subchondral bone resulted in flattening and indentation of cartilage, osteochondral fragmentation, and ultimately osteoarthritis (OA).^{7,9,20}

CLINICAL EXAMINATION

A pathological continuum of cortical and subchondral stress-related bone injury causes lameness, subchondral sclerosis, subchondral lucency, incomplete (stress or fatigue) and complete fracture, and, in horses with subchondral damage, the eventual development of OA. Clearly, early and accurate diagnosis of stress-related bone injury in racehorses is important for the well-being of the horse and the safety of the industry. However, clinical recognition of these injuries can be challenging, and, although stress fractures are a well-recognized cause of lameness in racehorses,^{11,15,16,25-34} most of these injuries occur in the absence of a specific traumatic event.^{3,8,15-17,30} Characteristic history includes acute onset of lameness after racing or training that responds to rest.^{25-27,30,35} Over time, lameness may worsen or linger, and some horses may have a history of weeks to months of poor performance, intermittent unilateral lameness or lameness in numerous limbs, or reports from exercise riders or drivers that horses are not "right."^{27,36,37} Lameness scores at the time of diagnosis are quite variable, with some horses exhibiting no lameness and others being severely lame. Physical findings such as swelling or sensitivity to palpation are often subtle or absent. This is especially true in horses with upper limb long bone stress fractures, in which palpation may be at best difficult.

Clinical signs of cortical bone injury include periosteal thickening and local sensitivity. This is easily recognized in horses with the bucked-shin complex³⁸⁻⁴⁰ (see Chapter 102). However, in the majority of long bones, overlying soft tissue and muscle prohibit clear identification. Localized signs of cortical pain in the tibia or humerus are uncommon and frequently absent.^{16,25,28,31} When noted, pain during palpation and percussion of the medial diaphysis of the tibia occurs in as few as 30% of affected horses.²⁵ Careful palpation may reveal focal pain in horses with avulsion fracture of the proximal palmar or plantar aspect of the McIII or the MtIII, respectively.⁴¹ Pain on palpation or profound muscle spasm of the affected side and ventral displacement of a tuber sacrale are consistent but subtle

physical abnormalities in horses with stress fractures of the wing of the ilium.^{15,30} Flexion tests, time-honored clinical tools to help exacerbate and localize lameness, often have inconclusive results, and findings may even be absent in horses with cortical bone injury.^{24,42}

Clinical signs of subchondral bone injury are also variable and often subtle. Injuries are frequently bilateral, and overt unilateral limb lameness is unusual. Affected horses may simply be performing at a lower level than expected. Overlying cartilage is minimally affected early in the disease process, and joint effusion is absent. Early subchondral bone injury of the distal aspects of the McIII and the MtIII rarely causes fetlock effusion,^{36,43-45} and carpal effusion is often less than expected based on severity of lameness in Standardbreds (STBs) with subchondral lucency of the C3.^{46,47} Diagnostic analgesia is essential for accurate diagnosis, but perineural techniques are consistently more effective than intraarticular analgesia, presumably because pain is associated with subchondral bone and not synovitis, capsulitis, and overt cartilage damage (see Chapter 42). Veterinarians and trainers are often incredulous when a diagnosis of subchondral bone injury is made by use of diagnostic analgesia and scintigraphic examination when clinical signs are lacking. As with cortical bone injury, flexion test results are inconsistent and often negative in horses with subchondral bone injury.^{36,46} Subchondral increased radiopacity may be radiologically apparent, but it is often difficult to determine whether this is successful adaptive change or a maladaptive or nonadaptive response. In those horses with severe or chronic subchondral bone injury, clinical signs are often more obvious. Synovitis, lameness, and OA may be noted.

DIAGNOSTIC ANALGESIA

Although diagnostic analgesia is one of the most valuable tools used to localize the authentic source of pain, there are several considerations in horses with stress fractures and subchondral bone injury. At the time of evaluation, horses must be lame enough to visually assess response to diagnostic analgesia. Horses with stress fractures are notorious for being lame immediately after intense exercise but subtly lame or sound at the time of lameness examination. Neither perineural nor intraarticular analgesia can be used to diagnose upper limb stress fractures; however, such fractures should be suspected when lameness cannot be improved by routine distal limb diagnostic analgesia.* In addition, response to diagnostic analgesia is often variable. Lameness associated with cortical or subchondral injury of the proximal palmar aspect of the McIII may improve with high palmar analgesia or intraarticular analgesia of the middle carpal joint.^{27,41,42,50} Pain associated with nonadaptive subchondral remodeling of the distal aspect of the McIII or the MtIII may be alleviated by using a low palmar or plantar or the lateral palmar metacarpal or plantar metatarsal block.⁵¹ Often these horses will not improve with intraarticular analgesia and are similarly unresponsive to intraarticular medications.^{36,43,44} Diagnostic analgesia is a good starting point but must not be used alone.

*References 25, 26, 28, 34, 48, 49.

DIAGNOSTIC IMAGING

Radiography and Radiology

Radiography remains hugely important in the diagnosis of bone injury in racehorses; however, it is insensitive during early phases of stress-related bone injury and often inadequate for subtle subchondral changes. Radiology provides structural information, much of which must be several weeks old before it can be seen. Lag time for enough structural change to occur to be seen radiologically is an obviously serious limitation of radiography, especially when one is attempting to localize and identify early or subtle bone injury. It takes 2 to 3 weeks or more before radiological changes of periostitis are apparent (see Chapter 15).⁵²⁻⁵⁵ Even frank fracture lines or compression injury of subchondral bone can take days to weeks to be recognized. Supplementary radiographic images of site-specific regions may enhance detection of injury. For example, the dorsal 30° proximal 45° lateral-palmar (or plantar) distal medial oblique and dorsal 30° proximal medial-palmar or plantar distal lateral oblique (“down-angled”) images (Figure 100-1) are useful for evaluation of subchondral injury of the condyles of the McIII or the MtIII.^{51,55} A dorsal 60° proximal 45° lateral-palmar distal medial oblique image or dorsal 60° proximal 45° medial-palmar distal lateral oblique image of the distal phalanx is necessary for identification of palmar process fractures.⁵⁶⁻⁵⁸ Even with additional images, subtle subchondral radiolucency and increased radiopacity are often difficult to recognize because density differences must be at least 30% to 50% and lesions 1 to 1.5 cm in diameter before recognition is possible.⁵² Another obvious limitation of radiography is the inability to distinguish whether the radiologically apparent lesion is an active process or simply the result of an adaptive bone response.

Fig. 100-1 • A dorsal 30° proximal 45° lateral-palmar distal medial oblique (“down-angled”) radiographic image of 3-year-old Standardbred with subchondral lucency (arrows) of the distal plantarolateral aspect of the third metatarsal bone.

Nuclear Scintigraphy

Increased awareness of location and prevalence of stress-related bone injuries and scintigraphic examination of affected racehorses enhance early detection of bone pathology before catastrophic fracture. Nuclear scintigraphy is an extremely sensitive method of detecting exercise-induced bone remodeling (see Chapter 19). Normal bone response in the dorsal aspect of the McIII, the proximal sesamoid bones (PSBs), and the metacarpal condyles is easily identified and has typical patterns of increased radiopharmaceutical uptake (IRU) in horses undergoing high-speed exercise.^{59,60} Scintigraphy is useful to detect abnormal alterations in local bone metabolism such as increased activity from cyclic loading and provides a foundation for the diagnosis of stress fractures, stress remodeling, and subchondral trauma.* A focal, moderate-to-intense area of IRU is the scintigraphic hallmark of stress fracture.

Several circumstances exist in which scintigraphy is invaluable for the diagnosis of cortical or subchondral bone injury. Racehorses with stress fractures often have a history of acute severe lameness that abates with rest. These horses have few localizing clinical signs and are diagnostic challenges. Scintigraphy can be used as a screening tool and obviates the need for numerous radiographic images. In addition, a negative bone scan is invaluable because it rules out active bone disease and virtually eliminates the possibility of a stress fracture.^{52,54} Another scenario is when a racehorse fails to respond to diagnostic analgesia. This is especially true in horses with upper limb stress fractures. Scintigraphy is also helpful for horses with bone injury in numerous areas or multiple limbs. Racehorses with stress remodeling of the distal aspects of the McIII or the MtIII are often in this category.

Scintigraphy is more sensitive than radiography for the identification of stress-related bone injury, and a positive bone scan may precede conclusive radiological change by at least 2 to 3 weeks.⁵²⁻⁵⁴ In reports of scintigraphic examinations of racehorses, nearly half of areas of IRU were not associated with radiologically detectable abnormalities.^{61,63,64} A positive bone scan may also enhance the recognition of subtle radiological changes⁴¹ and assist in determination of a structural abnormality as an active process or a reflection of past change. For example, radiographs of a 3-year-old TB racehorse reveal extensive thickening of the dorsal cortex of the McIII, but the bone scan is negative. Gradual resolution of IRU of the dorsal cortex of the McIII can be interpreted as evidence of satisfactory healing of a previously identified dorsal cortical fracture. On the other hand, a persistent fracture line without concurrent moderate-to-intense IRU may indicate the development of a nonunion, because the amount of radiopharmaceutical uptake reflects the rate of bony repair.²⁹ Carpal pain is not likely in a STB with radiological evidence of extensive sclerosis of the C3 but with only mild or no IRU seen scintigraphically.

Ultrasonography

Iliac wing fractures can be detected ultrasonographically.^{15,17,30,66,67} Hematoma formation, irregular bone contour (indicative of callus formation), and breaks in the

*References 25, 27, 31, 32, 35, 41, 52-54, 56, 60-65.

normal hyperechogenic contour of bone may be seen if the fracture involves the dorsal surface of the bone (see Figure 49-3, page 566). A displaced fracture is seen as hyperechogenic bony structure distracted from adjacent bone ("stair-step" sign). Ultrasonographic abnormalities are usually most severe at the caudal margins of the fracture.^{66,67} These findings are supported by postmortem studies in horses with ilial wing fractures.^{11,13} Serial ultrasonographic examinations can be used to determine if the fracture has healed but should not be the single means of diagnosis. Because of variability in conformation of the ilium and other factors, ultrasonographic findings should be combined with a thorough clinical examination and, if necessary, scintigraphic and occasionally radiographic examinations.^{15,66}

Magnetic Resonance Imaging and Computed Tomography

Slice-by-slice high-resolution images obtained during magnetic resonance imaging (MRI) detect alterations within bone early in a disease process before they are detectable by most other imaging modalities. In people, MRI is frequently used when conventional radiological findings are unremarkable, because MRI has better spatial resolution and specificity. Low signal intensity on T1- and T2-weighted gradient echo (GRE) or proton density (PD) images is the classic appearance of stress-related bone injury. Increased signal intensity in the trabecular and/or cortical bone on short tau inversion recovery (STIR) sequences or fat-suppressed T2-weighted fast spin echo sequences may reflect a bone contusion or fracture, depending on the distribution of altered signal intensity. Computed tomography (CT) may identify linear alteration in signal intensity in the cortex and endosteal and periosteal callus and is more sensitive than plain radiography. As with conventional radiography, false-negative findings are not uncommon. Obvious limitations of MRI and CT acquisition include costly equipment, often the need for general anesthesia, and the inability to image equine upper limbs and pelvis.

SPECIFIC LOCATIONS OF CORTICAL AND SUBCHONDRAL BONE INJURY

Knowledge of the prevalence of stress-related bone injuries provides insight into the likelihood of an area causing clinically important problems, especially when diagnostic analgesia fails to localize the lameness, or radiological and ultrasonographic examination findings are unremarkable. The type of training and racing largely determines the location of injury and whether the injury involves cortical or subchondral bone (Tables 100-1 and 100-2). In lame STBs, IRU is most commonly associated with exercise-induced subchondral bone remodeling, and prevalent sites include the PSBs followed by the C3 and the tarsus.⁶³ The distal palmar or plantar aspect of the McIII or the MtIII is also a frequent location of IRU and, when combined with IRU of the PSB, is the most common location of stress remodeling.^{55,63} In TBs, IRU of the distal palmar or plantar aspects of the McIII or the MtIII is the most common abnormal scintigraphic finding.⁶² In the forelimbs, sites of prevalence are the distal palmar aspect of the McIII, followed by the carpus and the dorsal cortex of the McIII.⁶² In the hindlimbs, the distal plantar aspect of the MtIII is the most common abnormal area, followed by the tarsus and tibia.⁶²

Distal Phalanx

IRU associated with the distal phalanx in the absence of radiological abnormalities in racehorses that subsequently developed distal phalanx fractures suggests that these fractures are not single-event injuries, but rather the result of repetitive stress.^{56,57} Clinical examination findings include unilateral lameness localized to the digit using palmar digital analgesia. A fracture usually results in acute, severe lameness. If the fracture is articular, distal interphalangeal

joint distention may be noted, and lameness is often alleviated by intraarticular analgesia.⁵⁸ Response to hoof tester application is variable and often unreliable. Distal phalangeal fractures occur more often in the forelimbs than the hindlimbs, and STBs may be overrepresented.^{56,57} The lateral aspect of the left front and the medial aspect of the right front distal phalanges are most commonly affected, a finding that may reflect compression of these sides of the distal phalanx during counterclockwise racing in the United States.⁵⁶⁻⁵⁸ The distribution of distal phalangeal fractures in racehorses from the United Kingdom or continental Europe is unknown.

Numerous scintigraphic images including lateral, dorsal, and solar images are recommended for complete and accurate diagnosis.⁵⁹ Oblique radiographic images of the palmar processes of the distal phalanx should be obtained to assist in identification of subtle radiolucent lines, particularly in horses with IRU identified scintigraphically.^{59,61}

Palmar or Plantar Aspects of the Metacarpophalangeal/Metatarsophalangeal Joints

The true incidence of distal palmar or plantar subchondral injury of the McIII or the MtIII is unknown (see Chapters 36 and 42). Scintigraphic studies have indicated as many as 50% of TBs⁶² and 20% of lame STBs may be affected.⁶³ Subchondral bone injury of the MtIII was identified as a major cause of hindlimb lameness in STB racehorses.⁵⁵ The proposed pathogenesis of subchondral injury to the distal palmar or plantar aspects of the McIII or the MtIII includes a progression of subchondral remodeling in response to repetitive stress including trabecular thickening (sclerosis). Under normal circumstances, this functional adaptation attenuates the load and spares stress on the articular cartilage. Under pathological conditions, this adaptation fails to protect the joint. Microcracking of the subchondral bone and cartilage⁶⁸⁻⁷⁰ and/or focal necrosis^{7,9} ensue, promoting the development of OA.

Subchondral bone changes in the distal aspect of the McIII or the MtIII may precede and predispose to condylar fractures.⁷¹ The adapted and thicker subchondral bone of the condyles is significantly stiffer than adjacent bone, which results in a gradient between the relatively less dense sagittal ridge and the condylar bone. Strain accumulation at this interface may lead to an increase of localized fatigue damage, predisposing it to catastrophic failure.⁷¹ Alternatively, larger cracks may be a manifestation of smaller microcracks, which originate in the sclerotic zone as part of the resorption phase of the remodeling response.²⁰ Regardless of the underlying chain of events, preexisting pathology such as focal regions of osteoporosis and microdamage in the surrounding bone have been identified in bones of horses with lateral condylar fracture of the McIII/MtIII.^{21,70,71} Fracture lines pass through areas of localized porosity.^{21,71}

Early in the disease process, when lameness is thought to be related to subchondral bone pain, abnormal physical examination findings are often lacking and clinical signs can be easily overlooked. Lameness is mild or apparent only at high speeds, joint effusion is uncommon, and most horses do not manifest a positive response to flexion tests.^{36,55} When the hindlimbs are affected a bunny-hopping type of gait or lack of impulsion may be noted

when horses canter.⁴⁵ In horses affected bilaterally, a short, choppy, uncomfortable gait or an intermittent, shifting hindlimb lameness may be present. Perineural analgesia is more effective than intraarticular analgesia in abolishing pain at this stage of the disease process. Either a low palmar or plantar or lateral (medial) palmar metacarpal or plantar metatarsal nerve block is recommended,⁵¹ because intra-articular analgesia of the fetlock joint inconsistently abolishes subchondral pain.^{36,43} Perineural analgesia in one limb will often result in horses then exhibiting contralateral limb lameness. Radiological evaluation is frequently unremarkable; however, IRU in the distal palmar or plantar aspects of the McIII or the MtIII is diagnostic if lameness has been localized using diagnostic analgesia. As the disease progresses, lameness worsens, and horses are more likely to have a positive response to a lower limb flexion test. Both a positive bone scan and abnormal radiological findings (increased subchondral radiopacity and radiolucency) are apparent. Later, joint effusion, more prominent lameness, and a positive response to intraarticular analgesia may be noted.

Scintigraphy is the method of choice for diagnosis as radiographs are often negative or equivocal, especially in the early stages of disease. Standing lateral, plantar, and flexed lateral scintigraphic images are recommended (Figure 100-2). The most common scintigraphic abnormality is focal IRU of the distal palmar or plantar aspects of the McIII or the MtIII, but the PSBs may be involved. Flexed lateral images are especially helpful to differentiate IRU of the distal aspect of the McIII or the MtIII from that involving the PSBs.⁵⁵ In a retrospective study of lame STBs undergoing scintigraphic evaluation, 20% of images had IRU associated with the palmar or plantar aspect of the fetlock joints.⁶³ It is not uncommon for more than one limb to be affected⁶² or for IRU to be identified in all four fetlock joints.⁶¹ Front and hind fetlock joints are commonly concomitantly affected.^{61,63} Metatarsophalangeal joint lameness may be more common in STBs because

Fig. 100-2 • A, Delayed phase lateral scintigraphic images of the distal aspect of the limbs of a 4-year-old Thoroughbred with focal, intense increased radiopharmaceutical uptake (IRU) in the palmar and plantar aspects of the metacarpophalangeal and metatarsophalangeal joints. **B,** The flexed lateral images confirm that IRU is confined to the distal palmar or plantar aspect of the third metacarpal and metatarsal bones, not the proximal sesamoid bones or the proximal phalanx.

Fig. 100-3 • Dorsal T2-weighted gradient echo magnetic resonance image of the right metatarsophalangeal joint of a 3-year-old Standardbred racehorse with moderate right hindlimb lameness, which subsequently improved with lateral plantar metatarsal analgesia. There is a hypointense signal (arrow) within the lateral condyle of the distal aspect of the third metatarsal bone, consistent with increased bone density.

of gait and load distribution, and IRU of the distal plantarolateral aspect of the MtIII predominates.⁵⁵ In TBs, IRU in the distal palmar aspect of the McIII is more common than IRU in the distal plantar aspect of the MtIII, and bilateral IRU is prevalent.^{61,62}

In addition to routine radiographic images of the metacarpophalangeal and metatarsophalangeal joints, “down-angled” oblique images are recommended for complete evaluation of the distal palmar or plantar aspects of the McIII or the MtIII.^{51,55} Less than half of horses with IRU will have radiological abnormalities.^{55,61,63} When apparent, bony changes include subchondral lucency and increased radiopacity (see [Figure 100-1](#)).^{45,55} Radiological evidence of lucency may represent a later stage of the remodeling process and may be indicative of necrotic subchondral bone.^{7,55}

Advanced imaging (MRI and CT) has improved our understanding of subchondral bone damage in fetlock joints and has great potential for early detection and implementation of management techniques directed toward injury prevention. Bony changes identified during MRI include small areas of high signal intensity within dense, sclerotic subchondral bone on STIR and T2-weighted images consistent with fluid, fibrosis, or bone necrosis within the subchondral bone and hypointense regions within the condyle on PD images consistent with increased bone density ([Figure 100-3](#)).⁷² Through the use of CT, subchondral increased radiopacity in the condyles^{59,69,71} and bone porosity at the site of condylar fracture^{69,71} have been identified in cadaver specimens.

Dorsal Cortex of the Third Metacarpal Bone

Stress-related bone injury of the dorsal cortex of the McIII (bucked-shin complex) is a well-recognized disease of

racehorses, particularly young TBs, in which incidence has been reported to be as high as 70%.³⁸ There are two clinical syndromes, diffuse periostitis (bucked shins) and dorsal cortical fracture (saucer, fatigue, stress fracture), thought to be closely related and representing a continuum of stress-related bone injury (see Chapter 102).

Race training in TBs results in repetitive loading on the McIII. The McIII then responds by modeling and remodeling, adding to and increasing the density of the dorsal cortex. Under balanced conditions, the dorsal cortex thickens, the minimum moment of inertia changes significantly, and the bone is then adapted.³ Histological examination of classically trained TBs shows that bone remodeling is confined to the dorsomedial surface of the bone.⁷³ If the modeling process is unable to keep up with bone strain, more bone stiffness is lost, and more periosteal new bone is formed. This resulting microdamage manifests itself clinically as “bucked shin.”⁷³ The relatively thinner dorsolateral cortex is subject to lower strains during race training, never responding with clinically significant modeling and remodeling. As the speed of training increases and the high-strain cycles accumulate, this thinner poorly adapted dorsolateral cortex may sustain incomplete cortical stress fractures.⁷³

Classically, TBs develop bucked shins early in training, at or about the time of high-speed work, usually in the 2-year-old year. Clinical signs are usually sufficient for diagnosis. The condition is characterized by pain, heat, and swelling on palpation of the dorsal aspect of the McIII.^{29,38,44,60} Frank lameness may be present, but subtle signs such as unwillingness to train at high speeds may be apparent.^{29,60} In North American TBs the left forelimb may be more commonly affected than the right, although the disease occurs bilaterally. This injury is rarely seen in older horses, especially those that have raced successfully. Racehorses trained and raced in Europe may develop bucked shins when they relocate to North American dirt tracks.⁴⁰ Once the condition is recognized and the horse recovers, it rarely recurs. Clinical signs of dorsal cortical fractures include firm protuberance on the dorsal aspect of the McIII, usually in the middle third of the diaphysis. Application of firm digital pressure often elicits pain. Dorsal cortical fractures usually develop some months after the acute phase of bucked shins and most commonly in 3-year-old TB racehorses. About 10% to 12% of horses with bucked shins will also have dorsal cortical stress fracture.^{38,40} Dorsal cortical fractures can occur along the proximal, middle, or distal dorsal aspects of the McIII but are most common in the middle third of the bone.

Although signs of dorsal McIII pain are common in TBs, STBs seldom exhibit it. In fact, TBs are 8.6 times more likely to develop dorsal metacarpal disease than STBs.⁶⁰ Bucked shins occasionally occur in pacers in June or July of the 2-year-old year and are unusual in trotters. Dorsal cortical fractures occur rarely, usually in 3-year-old pacers in the midportion of the racing year. Because mechanical properties of the McIII are not significantly different between STBs and TBs,³⁹ the disparity in prevalence is most likely the result of differences in training regimens between the breeds. STBs race at slower speeds than do TBs and in a different gait. In addition, STBs typically train long, slow jogging miles before introduction to speed work, unlike TBs, which typically have an earlier introduction of speed

Fig. 100-4 • Delayed phase standing lateral scintigraphic images of the distal forelimbs of a young Thoroughbred in active race training with normal, adaptive uniform and diffuse radiopharmaceutical uptake in the dorsal cortex of the third metacarpal bones (arrows).

work during training. When compared with the TB McIII, STB McIIIs are significantly more developed before onset of racing,³⁹ a finding that would explain an apparent resistance to the development of bucked shins in young STBs.

Radiological diagnosis of stress-related bone injury of the dorsal aspect of the McIII is often delayed after clinical diagnosis. When apparent, periostitis is identified by the presence of periosteal new bone (bony thickening or roughening) over the dorsal or dorsomedial aspect of the McIII. A diagnosis of dorsal cortical stress fracture is confirmed by the presence of a short, oblique, linear radiolucency at 30- to 45-degree angle to the dorsal cortex and is often noted in conjunction with periostitis. Well-exposed and well-positioned plain, digital, or computed radiographic views are required.

Mild, diffuse IRU in the dorsal cortex of the McIII is common in young TBs in training and is attributed to the rate of accelerated modeling that occurs in the McIII during training. Patterns of uptake considered a normal finding in these horses include mild, uniform, and diffuse IRU in the dorsal cortex of the McIII relative to the palmar cortex, but activity should be less than in the metaphyses (Figure 100-4).²⁹ Scintigraphic studies of racehorses evaluated for lameness indicated that 45% to 68% of TBs^{29,60} and 95% to 97% of STBs⁶⁰ have some IRU in the dorsal aspect of the McIII, but most of these horses do not have clinical signs of metacarpal pain. Periostitis (bucked shins) is evident by uniform and diffuse IRU in the dorsal cortex of the McIII relative to the palmar cortex and metaphyses (Figure 100-5).²⁹ IRU consistent with periostitis may be noted in as many as 12% to 34% of TBs^{29,60,62} and 1% to 3% of STBs.⁶⁰ Clinical signs of periostitis correlate well with scintigraphy; most horses with abnormal IRU also have metacarpal pain. Dorsal cortical fractures are evident as focal moderate-to-intense IRU in the dorsal cortex of the McIII^{29,60} (Figure 100-6) and are occasionally identified in combination with periostitis.²⁹ Focal IRU is a much more important finding in establishing the diagnosis of fracture than is intensity of IRU. In STBs, dorsal cortical stress fractures are exceedingly

Fig. 100-5 • Delayed phase lateral scintigraphic images of the distal forelimbs of a 3-year-old Thoroughbred with diffuse moderate increased radiopharmaceutical uptake (IRU) in the dorsal cortex of the third metacarpal bones (arrows). This pattern of uptake is consistent with a diagnosis of bilateral periostitis (bucked shins). The distal palmar aspects of both third metacarpal bones exhibit mild IRU as well.

Fig. 100-6 • Delayed phase lateral scintigraphic image of the distal right forelimb of a 3-year-old Thoroughbred with focal, intense increased radiopharmaceutical uptake in the dorsal cortex of the right third metacarpal bone. This pattern of uptake is consistent with a diagnosis of a dorsal cortical fracture.

uncommon, reported in only 1% of the population of lame horses undergoing scintigraphic examination.⁶⁰

Proximal Palmar Aspect of the Metacarpal Region

Proximal palmar metacarpal region pain is a common cause of forelimb lameness in athletic horses (see Chapter 37).^{27,35,41,42,50} Many pathological bony processes have been described, including avulsion fracture of the McIII at the origin of the suspensory ligament, palmar proximal cortical incomplete fracture of the McIII, and stress reaction or stress fracture of the McIII.^{27,35,41,42} The differential diagnosis is based on clinical findings, perineural analgesia, and diagnostic imaging. Scintigraphic, ultrasonographic, radiographic, and/or MRI examinations are often required to

confirm and categorize a diagnosis. Making a clear distinction between primary bony injury and secondary bone modeling that occurs in some horses with proximal suspensory desmitis can be challenging without MRI. Physical examination findings are often lacking.^{27,35,42,50,74} Moderate-to-severe lameness is the most consistently observed clinical sign* and typically occurs at or near racing speeds.^{27,42,50} Some horses respond to focal digital pressure on the proximal palmar aspect of the McIII,^{27,41,42,50,74} and few have evidence of heat or swelling.⁷⁴ Proximal palmar metacarpal region pain is confirmed by improvement in lameness severity after diagnostic analgesia. Multiple techniques for analgesia of this region include lateral palmar, high palmar, and subcarpal analgesia, local infiltration of the proximal palmar aspect of the McIII, and middle carpal analgesia.[†]

Radiological evaluation may reveal a plethora of bony abnormalities. The classic appearance of an avulsion fracture of the suspensory origin consists of a crescent-shaped radiolucent defect of the proximal aspect of the McIII seen on a dorsopalmar image. Incomplete longitudinal fracture is seen as a linear or slightly oblique radiolucency in the proximal aspect of the McIII, medial to the midline.^{35,42} Increased radiopacity of the subchondral bone is best identified on a dorsopalmar image and may be seen alone, in conjunction with fracture, or in association with bony modeling secondary to proximal suspensory desmitis. More subtle radiological findings such as periosteal reaction, enthesophyte formation, and small radiolucent defects in combination with positive scintigraphic findings are also diagnostic.

Focal moderate or intense IRU in the proximal palmar aspect of the McIII confirms the presence of stress-induced bone injury and may represent avulsion fracture,⁴¹ incomplete fracture,³⁵ stress reaction, or stress fracture of the McIII,²⁷ but can also be seen in association with acute, severe proximal suspensory desmitis. Radiological abnormalities are inconsistently identifiable in horses with IRU,^{27,35,41} and the clinical importance of subtle or questionable radiological abnormalities is enhanced with positive bone scan findings.⁴¹ Scintigraphy is quite useful for differentiation of middle carpal and carpometacarpal joint lesions, particularly in horses with lameness abolished by middle carpal analgesia.

Ultrasonographic examination is recommended for identification of confounding and/or contributing suspensory desmitis. Individual variation in size and shape of the proximal aspect of the suspensory ligament, artifacts, and variable amounts of muscular tissue complicate ultrasonographic interpretation. Ultrasonographic images underestimate ligament size because the medial and lateral margins are difficult to evaluate; they are less anatomically detailed than MRI images,⁷⁵ and low-grade lesions may be missed.

Recent experience with MRI has demonstrated superior ability to assess both soft tissue and bone injury in the proximal palmar aspect of the McIII.^{74,75} High signal intensity on STIR sequences is indicative of fluid or edema (bone contusion), fibrosis, or necrosis and may be caused by the bone's response to tearing of the origin of the proximal aspect of the suspensory ligament, but may also reflect primary osseous injury.⁷⁴ Low signal intensity on PD and

T2-weighted GRE images is indicative of increased bone density and may be a sign of chronic injury.⁷⁴

Subchondral Injury of the Third Carpal Bone

The C3 adapts to high-intensity exercise by increasing its subchondral density by bone modeling.^{22,76-80} The radial facet of the C3 is particularly vulnerable to repetitive loads encountered during race training (see Chapter 38).^{76,77,79} Histological changes include progressive thickening of the subchondral bone plate at the expense of medullary space that ultimately produces a bony bridge between the proximal and distal cortices.^{12,22} Although some degree of sclerosis is a normal adaptive response,²² continued modeling in response to loading may cause excessive increase in bone density. In horses with extreme sclerosis, cancellous bone appears to have been almost entirely converted into compact cortical bone, and abnormal dissipation of forces between articular cartilage and subchondral bone may ensue. With subchondral bone density increases, the shock-absorptive capacity decreases, predisposing to cartilage damage⁸¹ and OA. Cartilaginous lesions^{18,79} and reduced cartilage stiffness⁷⁹ have been noted in sites of maximal subchondral density; however, the interactive mechanism by which bone changes may affect cartilage, and vice versa, is disputed and the subject of intense study.

Modeling of the subchondral bone at the expense of the marrow and vascular spaces may also lead to ischemia of the subchondral bone,^{9,12,22} although the role of ischemia has not been clearly delineated and remains controversial. Further mechanical abuse to ischemic regions may cause progression to focal osteolysis and gross subchondral loss, predisposing to chip or slab fracture.^{9,12,22} Histological and/or gross sections of C3 slab fractures indicate that these injuries are pathological fractures, occurring in chronically damaged necrotic bony tissue.⁹

The localized increase in bone density is evident radiologically as increased radiopacity and loss of trabecular structure (sclerosis) on a dorsoproximal-dorsodistal oblique (skyline) image of the distal row of carpal bones. Histological evidence of increased subchondral bone density corresponds to increased radiopacity noted radiologically.^{22,77,82} and is usually localized to the radial fossa of the C3.^{82,83} C3 sclerosis and associated subchondral bone pain were implicated as an important cause of carpal lameness in STB and TB racehorses.^{46,63,83-85} In addition, increased radiopacity is seen in most horses with fractures of the C3.^{83,86} However, some degree of increased radiopacity represents a normal physiological adaptation to exercise, and not all horses with severe increased radiopacity are lame.^{22,84,85} Therefore the value of radiology and the clinical significance of increased radiopacity of the C3 can be questioned. The presence of IRU supports the clinical significance of radiologically apparent increased radiopacity of the C3.

Subchondral lucency of the C3, commonly in combination with increased radiopacity of the radial fossa, causes lameness in STBs.^{46,47,63,85} The pathogenesis is not clearly understood, but it may result from osteochondral collapse and cartilage damage because of chronic degenerative subchondral bone.^{46,82} Subchondral lucency is not a disease of racehorses in early training and may be the end result of a continuum of compression injury of the sclerotic C3.⁴⁶

The amount of sclerosis that can be considered physiological and how the transition to pathology can be

detected or prevented remain a major diagnostic dilemma. Therefore the clinical diagnosis of C3 subchondral bone injury can be challenging. The majority of horses with authentic subchondral C3 pain are lame, and often the degree of lameness is more pronounced than other clinical signs. As with other subchondral bone injuries, joint effusion, positive response to a carpal flexion test, and pain on palpation are often lacking.^{44,46,47,85} Horses with carpal pain tend to place the limb more widely than expected during protraction and may abduct the limb during advancement.^{44,46} Diagnostic analgesia in combination with well-exposed, well-positioned radiographic images and positive bone scan findings are recommended for diagnosis.

Scintigraphic examination reveals focal IRU of the C3 or the medial aspect of the subchondral bone of the middle carpal joint (Figure 100-7). Flexed dorsal images of the carpus help to differentiate IRU of the C3 from the radial carpal bone. In retrospective studies IRU of the C3 is common in lame STBs and frequently bilateral.⁶³ IRU in the C3 is also noted in TBs, and about one third of horses are bilaterally affected.⁶² Radiological evidence of increased radiopacity accompanies IRU in about half of injured horses.⁶³ Horses with focal, moderate-to-intense IRU are more likely to have radiological abnormalities (Figure 100-8).⁶³

Radius

Stress fractures of the radius are uncommon.^{26,62,63} They are usually unilateral and midshaft,²⁶ although bilateral fractures are seen occasionally.^{26,62} Enostosis-like lesions can mimic stress fractures and are seen more commonly in the radius than are stress fractures during scintigraphic evaluation (see Chapter 39).⁸⁷ Enostosis-like lesions are characterized by focal areas of IRU often close to the nutrient foramen and not involving the cortex.⁸⁷ Correct and careful positioning and/or additional images assist in differentiation.⁸⁷ Radiological abnormalities are typical for stress remodeling; periosteal bone reaction and fracture lines are identified infrequently. Enostosis-like lesions appear as

focal intramedullary radiopacities corresponding to areas of IRU (Figure 100-9).⁸⁷

Humerus

Complete, catastrophic humeral fractures in TB racehorses are now known to be associated with preexisting pathology (periosteal callus and incomplete fracture).⁶ Increased awareness of incomplete humeral stress fractures and scintigraphic examination of horses with undiagnosed forelimb lameness have enhanced early detection.

Stress fractures of the humerus are relatively common in young TB racehorses in early or mid training,^{2,6,25,26} and half of affected horses are unraced before diagnosis.²⁵ Race training after a lay-up period may be a predisposing factor, because return from lay-up has been strongly associated with increased risk of complete humeral fracture.² Initially, stress fractures of the humerus were reported

Fig. 100-10 • **A**, Lateral delayed phase scintigraphic image of the left elbow region of a 3-year-old Thoroughbred with focal, intense increased radiopharmaceutical uptake in the distal cranial aspect of the humerus (*arrow*). **B**, In merged cranial delayed phase scintigraphic images of the right and left shoulder regions, the increased radiopharmaceutical uptake is more prominent on the distal medial aspect of the left humerus (*arrow*).

more commonly in the left forelimb,²⁶ but more recent studies showed no difference between left and right forelimbs.^{6,25} Bilateral humeral stress fractures and recurrence are uncommon.^{25,26} The prevalence of humeral stress fractures in STBs is low and the location and conformation of stress-related bone injury of the humerus in STBs may be different than that of the TB.^{34,63} Differences in training and racing regimens may be responsible for the low prevalence of humeral stress fractures in STBs.

Most affected horses are unilaterally lame.^{25,26,34} Typical of horses with stress fractures, lameness is often severe immediately after exercise and improves quickly with box rest.^{25,26} Lameness may be more severe than with stress fractures elsewhere in the forelimbs. Physical examination findings are generally unremarkable, and few affected horses show pain during upper limb manipulation.^{25,34} Lameness is not abolished with distal limb analgesia^{25,26,34} and may become worse.²⁵ Intrathecal analgesia of the bicipital bursa may partially improve lameness severity in horses with stress fractures of the proximal aspect of the humerus because of diffusion of local anesthetic solution.³⁴

Nuclear scintigraphy is the most sensitive method to diagnose humeral stress fractures; there is focal IRU in the humeral cortex.^{25,26,34} The caudoproximal^{25,26} and the craniodistal^{25,34} aspects of the humerus and usually the medial cortex are the most common sites (Figure 100-10). Rarely, areas of IRU that are seen extending from the proximal caudal cortex to the distal cranial cortex of the humerus are highly suggestive of an incomplete spiral fracture. The scintigraphic pattern generally follows the same pattern as complete humeral fractures.⁶ Radiological examination is less sensitive, positive in only half of horses with focal IRU associated with the humerus, but is more specific than scintigraphy.²⁵ Callus formation and less commonly a distinct fracture line may be noted (Figure 100-11).

Fig. 100-11 • Lateromedial radiographic image of the left elbow region showing callus formation (*arrows*) along the distal cranial aspect of the humerus consistent with a healing stress fracture.

Scapula

Postmortem examination has identified scapular stress fractures as singular and focal and occurring along the distolateral aspect of the scapular spine.¹³ Periosteal callus, indicative of preexisting bone stress, is also found in association with complete fractures.¹³ Although rare, stress fractures of the scapula should be considered when an upper forelimb stress fracture is suspected clinically.^{48,49} Affected TB racehorses have a history typical of other stress-related bone injuries—acute unilateral forelimb lameness after racing or speed work.^{48,49} To date, scapular stress fractures remain unreported in STBs. Few localizing clinical examination findings are apparent. Injured horses

have a negative response to diagnostic analgesia of the distal limb and infrequently a positive response to upper limb manipulation.^{48,49} Diagnosis is confirmed scintigraphically with focal, intense IRU in the scapula along the caudal ventral aspect,⁴⁸ the middistal spine of the scapula, or the supraspinous fossa.⁴⁹ Radiological abnormalities are difficult to detect in horses with proximally located stress fracture but may be apparent in those with distal fractures. Ultrasonographic examination may reveal bony irregularity and/or a “stair-step” appearance of the site of injury.

Tibia

Tibial stress fractures occur predominately in TBs and are one of the more common causes of acute hindlimb lameness in the racehorse.^{25,26,88} Tibial stress fractures occur infrequently in STBs and Quarter Horses.^{16,26,28,31,89} Most tibial stress fractures occur during race training, and in one study, more than half of affected horses had had at least one 60-day lay-off period within the last three starts before injury.^{32,33} Most affected horses are 2- or 3-year-olds,^{25,28,32,33} but fractures occur in older TBs and STBs as well.^{26,28,89} Fractures may occur unilaterally and are seen equally in the right and left hindlimbs. However, unilateral lameness may be associated with bilateral fractures. Fractures occur in a variety of locations, including proximocaudal, mid-diaphyseal, and distomedial.* Bilateral lameness and bilateral fractures may occur,^{25,31,32,88} and fractures can occur in the contralateral tibia at a later date.²⁵ Tibial stress fracture can propagate to a complete fracture even with enforced stall confinement.³²

Typically, horses have moderate-to-severe acute lameness after racing or training.[†] Affected horses may be more lame than horses with stress fractures in other locations and should be suspected of having a tibial stress or spiral fracture if acute non-weight-bearing hindlimb lameness is present. There are few localizing signs on physical examination. Some affected horses have a positive response to firm pressure and percussion of the medial diaphysis of the tibia.²⁵ Horses may have a positive response to upper limb flexion^{16,25,26,31} and pain when torsion is placed on the tibia.⁴⁵ History and a negative response to diagnostic analgesia in the remainder of the limb are important.^{25,26,28}

Tibial stress fractures are identified as focal areas of IRU, and numerous sites of injury have been described.[§] The thickness of the soft tissue overlying the lateral aspect of the midcrus may impede detection in all affected horses in lateral images; therefore additional caudal or oblique images are recommended for horses with subtle areas of IRU in the tibia and in those in which there is a high index of suspicion but no convincing area of IRU is seen in standard images. The most common site of IRU is in the caudolateral aspect of the middiaphysis (Figure 100-12) or the proximocaudal aspect of the tibia.[‡] Stress fractures of the caudomedial cortex may occur but are uncommon. Occasionally, diffuse areas of IRU in the distal aspect of the tibia are seen with spiral tibial stress fractures (Figure 100-13). Postmortem studies correlate with scintigraphic findings and have identified periosteal callus in a variety

of locations.¹³ Radiological examination can confirm diagnosis in the majority of but not in all horses.^{25,28,31,32} Radiological abnormalities include cortical thickening, periosteal or endosteal bony reaction, and an oblique cortical fracture line.*

Ilium

The ilium is the most common site of stress-related bone injury in the pelvis (see Chapter 49).^{11,13,15,17,67} Within the ilium the most frequent site is 10 to 15 cm lateral to the

Fig. 100-14 • Dorsal delayed phase scintigraphic image of a 3-year-old Thoroughbred with moderate, focal increased radiopharmaceutical uptake (arrow) in the right ilium. This is a common area of uptake seen in racehorses with stress fractures of the ilium. Cranial is to the top of the image.

tuber sacrale.¹⁵ Fractures usually originate at the caudal border of the ilium near the sacroiliac joint and course in a craniodorsal or cranio-lateral direction.¹¹ They may be unilateral and incomplete; however, bilateral injury is frequently seen.^{11,15,67} Horses usually sustain an ilial stress fracture during race training,^{2,33} and female and older racehorses are more likely to be affected, although this prevalence is derived from postmortem specimen data.^{2,11} Fractures extending into the ilial shaft are occasionally seen, especially in National Hunt racehorses in Europe, and horses with this type of ilial stress fracture have a more guarded prognosis than those with fractures limited to the ilial wing.

Initially, most affected horses are lame, although lameness severity varies and lameness often resolves rapidly within 24 to 48 hours.^{15,30,67} Shortened stride, hunched up back, and plaiting may be apparent.^{15,67} Mildly affected horses may lack propulsion and exhibit poor action behind without overt lameness.¹⁵ Horses may exhibit pain on palpation of the tuber sacrale on the affected side.^{15,30,67} Subtle, ventral displacement of the ipsilateral tuber sacrale may be noted when fracture is complete, but this clinical finding is easily missed.^{15,30,67} Muscle atrophy and resultant asymmetry of the sacral region may also be noted in horses with chronic fractures. Rectal palpation is useful if the fracture involves the ilial shaft and is complete. Gentle rocking of the pelvis while palpating may reveal the presence of crepitus or hematoma with complete fractures.⁶⁷

Scintigraphic evaluation reveals marked, focal IRU associated with the ilial wing, just lateral to midline (Figure 100-14). Right and left dorsal oblique images of the pelvis enhance the diagnosis by decreasing superimposition and improving image geometry of surrounding structures (Figure 100-15).^{12,91} Less commonly there is linear IRU extending from the tuber coxae axially along the caudal cortex of the ilial wing. Fractures of the ilial shaft may be more difficult to detect because of the greater overlying

Fig. 100-15 • Right oblique delayed phase scintigraphic image (cranial is to the right) of the same horse as shown in Figure 100-14. Increased radiopharmaceutical uptake consistent with an ilial stress fracture (arrow) can readily be seen.

muscle mass resulting in shielding; subtle IRU consistent with a fracture is easily overlooked.

Ultrasonographic examination has been discussed previously (see page 937). Pelvic radiography is useful only for diagnosis of complete ilial stress fractures and requires general anesthesia in most horses. However, diagnostic images of the tuber coxae, the ilial shaft, the acetabulum of the pelvis, and the ischium can be obtained in a standing, sedated horse.

Lumbar Vertebrae

A postmortem study of Californian TBs identified lumbar vertebral stress fractures in 50% of specimens.¹¹ Lesions were characterized by incomplete fracture and focal periosteal proliferation. Vertebral laminar stress fractures were mostly unilateral, and affected specimens tended to be from older horses. All vertebral stress fractures were continuous with vertical articular clefts of the cranial articular facets, near the junction of the dorsal spinous process in most. They were positively associated with the severity of both impingement of dorsal spinous processes and OA of synovial articulations. Although they were a common postmortem finding, the clinical prevalence is less in a normal racing population. Antemortem physical examination findings of affected horses are vague at best. Nonspecific signs of back pain such as poor performance, hunched-up lumbar spine, and poor hindlimb propulsion may be noted. Scintigraphic abnormalities of the lumbar vertebrae are not common.⁹² There is focal intense IRU in the affected vertebra; a dorsal image can help to determine if the lesion is on the left or the right. Radiological examination may reveal marked enlargement of the affected synovial articulation and a generalized increase in radiopacity.

Chapter 101

Bone Biomarkers

Joanna Price

Bone is a complex tissue that undergoes change throughout life by the processes of bone formation by osteoblasts and bone resorption by osteoclasts.¹ Modeling and subsequent remodeling of bone are required for bone health and allow the skeleton to respond rapidly to changes in its internal and external environment. Bone formation and resorption of bone are “coupled”²; the cycle of remodeling begins with the recruitment of osteoclasts, which attach to the bone surface and resorb the subjacent bone matrix. After osteoclasts evacuate a resorption pit, osteoblasts differentiate from mesenchymal precursors and fill in the lacuna with new bone matrix.³ In a healthy adult skeleton, formation and resorption are balanced. However, the balance is changed during growth, in response to altered exercise, by hormonal changes, during ageing, after therapeutic intervention, in metabolic bone disease, in neoplasia, and in response to injuries such as stress fractures.⁴⁻⁶ Changes in subchondral bone metabolism are also potentially important in the pathogenesis of osteoarthritis (OA).^{7,8} A challenge is to develop sensitive and specific noninvasive methods to detect changes in bone turnover in vivo. Abbreviations used in this chapter are summarized in [Box 101-1](#).

Changes in bone mass and structure are assessed using techniques such as quantitative ultrasound (QUS), dual energy x-ray absorbiometry (DEXA), and quantitative computed tomography (QCT).⁹⁻¹¹ However, it may take several months for changes in bone mass and architecture to be of a sufficient magnitude to be detected with these methods. Furthermore, QCT and DEXA are not straightforward to use in a conscious horse, and use is restricted to ex vivo or in vivo research studies. Magnetic resonance imaging (MRI) is being used increasingly to study bone pathology in people,¹² but in a standing horse it can be used only for the distal aspect of the limb. It is expensive and not appropriate for screening potentially at-risk populations. In contrast, bone biomarkers measure dynamic changes in bone cell activity and can be measured in body fluids using relatively inexpensive straightforward methods. Biomarker measurements can be repeated at frequent intervals and so are convenient to use in the field. Although bone biomarkers remain predominantly research tools, considerable investigation has been undertaken on potential clinical applications. Soon it is highly likely that selected biomarkers will be used in conjunction with other tools to identify at-risk horses.^{13,14}

Ideally, a biomarker should be measurable in body fluids by a sensitive and specific technique and be specific to its tissue of origin. Detailed molecular characterization of bone has led to the development of biomarkers with

increased specificity. Progress in equine bone biomarker research has been led by work in people—in particular, use of biomarkers to detect osteoporosis.¹⁵⁻¹⁷ There are a number of equine-specific assays, but most assays in use were originally developed for people.

Bone biomarkers are generally classified as markers of bone formation or markers of bone resorption or degradation, although some reflect changes in both processes ([Tables 101-1](#) and [101-2](#)). In general, bone biomarkers are enzymes expressed by osteoblasts or osteoclasts or organic components released during the synthesis and resorption of bone matrix.¹⁵⁻¹⁷ However, many bone biomarkers are present in tissues other than bone and may therefore be influenced by other physiological processes. Because each biomarker may reflect a different physiological process, it is preferable to assay for a combination of markers, as this will provide more information on bone (re)modeling. However, human studies have shown that in certain diseases individual markers give more useful information than others,¹⁵ and the same may be true in horses. Other criteria that determine the value of any biochemical marker are whether the factors that control its synthesis and metabolic pathway are understood and what factors influence its biological variability. For many biomarkers used in human clinical studies, surprisingly little is known about the regulation of synthesis and metabolism, and in horses even less is understood about these variables.

BOX 101-1

Abbreviations

ALP	Alkaline phosphatase
BALP	Bone-specific alkaline phosphatase
BGP	Bone gla-protein
BMD	Bone mineral density
CTX	Type I collagen C-terminal telopeptide
DEXA	Dual-energy x-ray absorbiometry
DMD	Dorsal metacarpal disease
DPD	Deoxypyridinoline
GGHyl	Glucosylgalactosylhydroxylysine
Ghyl	Galactosylhydroxylysine
HPLC	High-performance liquid chromatography
Hyp	Hydroxyproline
ICTP/CTX-MMP	Carboxy-terminal cross-linked telopeptide of type I collagen
IGF-1	Insulin-like growth factor 1
IRMA	Immunoradiometric assay
MRI	Magnetic resonance imaging
NTX	Type I collagen N-terminal telopeptide
OA	Osteoarthritis
OCa	Osteocalcin
PICP	Carboxy-terminal propeptide of type I collagen
PINP	Amino-terminal propeptide of type I collagen
PYR	Pyridinoline
QCT	Quantitative computed tomography
QUS	Quantitative ultrasound
RIA	Radioimmunoassay
WGL	Wheat germ lectin

TABLE 101-1

<i>Bone Formation Biomarkers</i>				
BIOMARKER	METHODS USED	BODY FLUID	SOURCE	COMMENTS
Bone-specific alkaline phosphatase (BALP)	ELISA	Serum SF	Bone	Some cross-reactivity with liver ALP?

<i>Bone Resorption Biomarkers</i>				
MARKER	METHODS USED	BODY FLUID	SOURCE	COMMENTS
Deoxypyridinoline (DPD)	HPLC ELISA	Urine Serum	Mature collagen in bone and dentin	Good specificity
Carboxy-terminal cross-linked telopeptide of type I collagen (ICTP, CTX-MMP)	RIA	Serum	Type I collagen	May be contribution from tissues other than bone
Carboxy-terminal cross-linking telopeptide of type I collagen (CTX-I)	ELISA ECLA	Urine Serum SF	Type I collagen	May be contribution from tissues other than bone
Collagen I (Col 1)	Indirect determination by subtracting Col CEQ from C1, 2C (both measured by ELISA)	Serum SF	Type I collagen	May be contribution from tissues other than bone

ECLA, Electrochemiluminescence assay; ELISA, enzyme-linked immunosorbent assay; HPLC, high-performance liquid chromatography; RIA, radioimmunoassay; SF, synovial fluid.

BIOMARKERS THAT REFLECT CHANGES IN BONE FORMATION

Bone formation biomarkers are synthesized by osteoblasts and reflect different aspects of osteoblast activity. They are all measured in serum or plasma (see Table 101-1).

Bone-Specific Alkaline Phosphatase

Alkaline phosphatase (ALP) is associated with the plasma membrane of osteoblasts and is required for osteoid formation and matrix mineralization.¹⁸ Total serum ALP is derived from numerous sources and is not a specific marker of bone formation. However, because posttranslational modifications of tissue-specific ALP (which encodes bone, liver, and kidney isoforms of ALP) occur, different methods have been developed that enable separation and quantification of these isoforms. Although numerous techniques exist to characterize equine ALP isoenzymes, electrophoresis and precipitation of bone-specific ALP (BALP) with wheat germ lectin (WGL) are used most commonly.^{19,20} The WGL assay is more specific than a human immunoradiometric (IRMA) assay, which shows some cross-reactivity with liver ALP in horses.¹⁹ However, other, more user-friendly human immunoassays have now been validated for use in horses.²¹ BALP predominates in serum during growth, and this is reflected in the high concentrations of BALP measured in young horses, although the proportion of the bone isoform decreases to approximately 50% in

adults.²² The observation that ALP activity in subchondral bone is increased in equine osteochondrosis²³ provided the first indication that BALP may be a useful marker for analyzing changes in subchondral bone associated with equine joint disease (BALP as a potential biomarker for joint disease is discussed in a later section).

Osteocalcin

Osteocalcin (OCa), which is otherwise known as *bone gla-protein* (BGP) is the most abundant noncollagenous protein in bone matrix, and a small fraction is released into the circulation after synthesis by osteoblasts. The only other cells to express OCa protein are odontoblasts and hypertrophic chondrocytes, so OCa has tissue specificity, and it has been widely used as a sensitive and specific marker of osteoblast function in human clinical studies. Numerous studies have described the measurement of OCa in horses and the factors that influence OCa levels.²⁴⁻²⁷ Several methods have been used to measure OCa in horses, and a number of equine-specific assays have been developed; recently I used a competitive human immunoassay that has been validated for equine use.²⁸ OCa is highly labile; therefore samples should be processed rapidly (within 90 minutes). For OCa assays, equine serum can be stored at -20°C for up to 26 weeks, although long-term storage should be below -25°C .²⁹ OCa levels are affected by general anesthesia; therefore sampling during surgery may give misleading results.³⁰

The Carboxy-Terminal Propeptide of Type I Collagen

Type I collagen is the most abundant collagen in bone, and the procollagen molecule contains both amino (PINP) and carboxy-terminal (PICP) extension domains, which are split off before fibril formation and released into the circulation. These propeptides provide quantitative measures of newly synthesized type I collagen, and in people serum levels reflect the rate of bone formation. PICP can be measured in horses by human radioimmunoassay (RIA).³¹ However, type I collagen is not bone specific, and synthesis in other soft tissues may contribute to PICP concentrations in serum. For example, increased levels have been observed after tendon injury,³² and there is a peak in PICP levels during rapid weight gain in growing Thoroughbreds (TBs).³³ Unfortunately, the human PINP assays that I have tested to date do not appear to show species cross-reactivity.

BIOMARKERS THAT MEASURE CHANGES IN BONE RESORPTION

The majority of bone biomarkers that reflect osteoclastic resorption of bone matrix are degradation products of type I collagen (see Table 101-2). Originally, collagen-related resorption biomarkers were measured in urine samples collected over a 24-hour period, but in practice this is difficult in the horse. More recently developed resorption markers can be measured in serum and synovial fluid.

Cross-Linked Collagen Telopeptides

Cross-links are located at the amino (N-) and carboxy (C-) termini in the type I collagen molecule, and a number of peptide assays have been developed for measuring telopeptides generated during osteoclastic resorption. The first of these was a RIA for the carboxy-terminal telopeptide of type I collagen (ICTP), which works well for serum of the horse. Because the enzyme cathepsin K cleaves the telopeptide, the assay is now abbreviated to CTX-MMP.¹⁶ I and others used ICTP quite extensively in early bone biomarker studies in horses.^{31,33-35}

More recently an immunoassay (CTX) was developed that recognizes ICTP containing an isoaspartyl peptide bond³⁶ and has been used increasingly in equine studies.^{37,38} In people, CTX has been widely used to monitor changes in bone remodeling in osteoporosis and in joint disease,^{15,37} although concentrations are affected by diet.

Other Biomarkers of Bone Resorption

A number of other biomarkers have been used to monitor bone resorption in the horse, including hydroxyproline (Hyp), hydroxylysine glycosides, and the pyridinium cross-links of collagen.³⁹⁻⁴² Pyridinoline (PYD) or hydroxylysyl pyridinoline (HP) is found in cartilage, bone, ligaments, and vessels, whereas deoxypyridinoline (DPD) or lysyl pyridinoline (LP) is found almost exclusively in bone and dentin.⁴³ During osteoclastic resorption the cross-links are cleaved and the components released into the circulation. Pyridinium cross-link concentrations measured in serum and urine are mainly derived from bone, and for many years urinary DPD, measured by high-performance liquid chromatography (HPLC), was considered the gold standard of resorption markers in human clinical research. HPLC

also provides a reliable method for measuring total urinary DPD and PYD concentrations in the horse. There are age-related decreases in PYD and DPD levels and a significant diurnal pattern in excretion.⁴⁴ In a study of acute tendon injury, urine PYD and DPD concentrations were increased, which probably reflects increased bone resorption associated with disuse.⁴⁰ I have used HPLC to measure DPD and PYD in horse serum, but this assay can be used reliably only in horses younger than 2 years of age, because serum concentrations in skeletally mature horses are below the limit of detection.⁴¹ A human immunoassay was used to measure the free fraction of equine urinary DPD, and this assay can be adapted for the measurement of serum DPD.^{45,46} Type I collagen degradation can also be determined indirectly by subtracting concentrations of a specific type II collagen degradation biomarker, Co1 234CEQ,⁴⁷ from concentrations of a biomarker that measures degradation of both type II and type I collagen (originally called COL2-3/4C_{short}, now referred to asC1,2C).⁴⁸

FACTORS THAT INFLUENCE BIOCHEMICAL MARKERS OF BONE CELL ACTIVITY IN HORSES

Because bone markers reflect instantaneous changes in bone cell activity, a large number of factors can be a source of preanalytical variability—controllable factors (e.g., food intake, circadian changes, or exercise) and uncontrollable factors (e.g., gender, age, or intercurrent disease).⁴⁹ A failure to define and appropriately manipulate controllable sources of variability and to account for uncontrollable variability limits interpretation of the results of bone marker measurements in clinical studies. Fortunately, the analytical variability of the assays is low if carried out by a specialist laboratory.

Circadian Variability

Human studies have shown that circadian variability may have a significant effect on markers of bone turnover, particularly urinary markers of bone resorption.⁴⁹ These circadian rhythms can be affected by age, disease, fasting, and drugs. Circadian rhythms in urinary PYD and DPD excretion have been described in adult geldings with peak levels occurring between 02.00 and 08.00—a pattern of change similar to that described in people.⁴⁰ In a study of six 2-year-old TB mares, changes in three bone biomarkers (OCa, ICTP, and PICP) and insulin-like growth factor 1 (IGF-1) were measured over a 24-hour period. There was a significant circadian rhythm for OCa (estimated peak at 09:00) and IGF-1 (estimated peak at 17:30) but no significant circadian rhythm for PICP or ICTP.⁵⁰ Others had previously described circadian rhythmicity in OCa levels in horses of different ages, although this remains somewhat controversial.^{25,40,51} Light may also influence OCa concentrations.²⁵ No circadian variability in CTX concentrations was found.⁵¹ I recommend collecting samples at a similar time of day, preferably first thing in the morning before exercise.

Diet

Human studies have shown that fasting significantly reduces the circadian variation in serum levels of CTX.⁵² To date, no effect of feeding on bone biomarkers has been described. Little is known about the influence of diet on bone turnover markers in horses; no short-term effect on

Oca concentrations was found after feeding.²⁵ Calcium supplementation has been found to suppress bone turnover in women.⁵³ Dietary mineral supplements, widely used in horses, may influence bone markers.

Seasonal Changes

Time of year may influence bone turnover in horses, and this may be particularly important during growth. Monthly variability in ALP and OCa concentrations has been found in Finnhorse foals⁵⁴; bone turnover markers in TB yearlings have been found to increase between midwinter and early summer.³³ A similar seasonal pattern of change in OCa was seen in a longitudinal study of 30 Ardenner horses from approximately 1 to 2 years of age.³⁷ CTX-I concentrations are also affected by season, with levels reaching a nadir in November before rising from November to April. In TBs the influence of season on bone biomarkers declines with age. Bone biomarkers were measured every month in more than 100 2-year-old TBs, and season did not have a significant effect on OCa, PICP, or ICTP concentrations.³⁴

Age

In horses, as in people, bone biomarkers are higher during skeletal growth than in adults. I do not know if bone turnover increases in old horses as it does in people. An inverse relationship with age was described for several bone biomarkers in different horse breeds including OCa,* BALP,^{19,22,31} PICP, ICTP,^{33,34,56} PYD, and DPD.⁴⁴ The decrease in bone turnover markers is most substantial during the first year of life, but levels do not plateau until 3 to 4 years of age. Comparison of ICTP, PICP, and OCa changes with age in early- and late-born foals showed that age-related decreases in these biomarkers were more distinct in late-born foals,⁵⁶ indicating a difference in the rate of skeletal development in foals born at different times of year. This may reflect increased activity in late-born foals that were turned out to pasture immediately after birth, whereas early-born foals were initially kept confined. Generally, biomarkers of bone formation and bone resorption have a similar pattern of change, because bone remodeling involves resorption of bone at some sites (e.g., the endosteum) and formation at others (e.g., periosteal surfaces and the metaphyses). However, an age-related decrease in CTX-I concentrations is not observed. There was no effect of age on CTX-I concentrations in 30 Ardenner horses 1 to 2 years of age³⁷; however, levels increased at 2 to 52 weeks of age.^{38,57} These results call into question the bone specificity and thus the value of this biomarker in the horse.

Any study of bone biomarkers must control for the effects of age, especially in young horses. Serial marker measurements (i.e., use of the horse as its own control) are likely to be most informative in young horses. Ideally each laboratory should establish its own reference ranges for each marker in horses of different ages. Published reference ranges are of questionable value because absolute levels of these biomarkers vary significantly among laboratories.

Gender

In people there are gender differences in bone biomarkers, and these vary with age.⁴⁹ In horses this may depend on the specific biomarker and/or the horse's age. There were

higher OCa levels in TB fillies of 24 to 36 months of age, but no gender difference was observed in younger horses.⁵⁵ There was no effect of gender on OCa and CTX-I concentrations,³⁷ on OCa concentration in Standardbreds of different ages,²⁴ or on OCa or ICTP concentrations in Warmblood or draft horses older than 4 years of age.²⁶ However, in a longitudinal study of 2-year-old TBs in race training in the United Kingdom (84 colts and 63 fillies), ICTP and OCa concentrations were higher in colts than in fillies, but there was no gender difference in PICP concentrations.³⁴ Lower biomarker concentrations in fillies may reflect smaller bone size and/or earlier sexual maturation.

Pregnancy, Lactation, and the Estrous Cycle

The calcium requirements during pregnancy and lactation are met, at least in part, by changes in maternal bone turnover, and in people an increase in markers of bone resorption precedes an increase in markers of bone formation.⁵⁸ Although not extensively studied in horses, OCa levels were unchanged in Selle Francais mares during the first 5 months after birth.⁵⁹ Bone cell activity in people is regulated by sex hormones.⁶⁰ In horses both OCa and ICTP concentrations were higher during the luteal phase of estrus,⁶¹ which is consistent with lower estrogen concentrations being associated with increased bone turnover. The stage of estrus must be considered as a potential source of uncontrollable variability in bone biomarker concentrations in horses as in people.⁴⁹

Breed

Ethnic differences in bone turnover have been described in people,⁴⁹ and horse type must also be considered as a potential effect on bone markers. The concentrations of OCa were lower and ICTP levels higher in draft horses compared with Warmbloods²⁶, which may relate to different rates of bone remodeling. This is not surprising considering the wide variation in skeletal size between different types of horse.

Intercurrent Disease

Little is known about the effect of different diseases on equine bone biomarkers. Any condition that affects bone metabolism (e.g., nutritional hyperparathyroidism) or marker clearance (e.g., kidney disease) will influence marker concentration. Liver disease may lead to increased cross-reactivity of BALP assays with the liver isoform of ALP. Fortunately these diseases are not common in equine athletes. However, an unrelated undiagnosed disease could contribute to circulating levels of a biomarker and misinterpretation of results.

CLINICAL APPLICATIONS FOR BONE BIOMARKERS

Bone biomarkers have been used in human medicine to study metabolic bone disease, particularly postmenopausal osteoporosis,^{16,17} for prediction of fracture risk and bone loss, and for monitoring the effects of therapy.⁶²⁻⁶⁴ The most valuable clinical applications for bone biomarkers in the horse, particularly if measured serially in the same horse, will be for identification of horses at risk of injury or for monitoring the effects of treatment. An important research application is to monitor the effects of exercise on

*References 24, 26, 37, 38, 55, 56.

the equine skeleton. However, because bone biomarkers reflect turnover in the *whole* skeleton and are affected by numerous variables there will always be an overlap between marker levels in normal and affected horses. Thus, in my opinion, it is unlikely that any bone biomarker measured as a “one off” will be able to function as a diagnostic test with a high level of discriminatory power.

Bone Biomarkers and Fracture

In order to assess bone biomarkers as predictors of risk of fracture (or any other condition), prospective studies are required that relate baseline bone biomarker levels to subsequent risk of injury. Bone biomarkers can be used to predict osteoporotic fracture in people.^{62,63} In a prospective study bone biomarkers (ICTP, PICP, CTX-I, and OCa) were measured at the start of the training season in more than 500 2-year-old and more than 300 3-year-old flat racehorses to determine if fracture could be predicted in the subsequent training season.⁶⁵ The incidence of fracture was 11.6% (60 horses) but the bone biomarkers measured were unable to identify horses that sustained a fracture. Measurement of bone biomarkers longitudinally (monthly) in flat racehorses in training also failed to demonstrate a relationship between biomarkers and fracture.⁶⁶ However, a field study of horses in training undertaken in the United States showed a relationship between biomarkers and injury risk.⁶⁷ Whether bone biomarkers have better predictive value in older horses when the biological variability associated with skeletal growth is reduced remains to be determined.

Bone Biomarkers and Dorsal Metacarpal Disease

Dorsal metacarpal disease (DMD) is a common problem in young racehorses associated with accumulated distance trained at canter and high speed.⁶⁸ In a study of 165 2-year-old TBs in training it was demonstrated that bone biomarkers measured at the start of training may have value for identifying horses at risk of developing DMD in the subsequent training and racing season.⁶⁹ OCa, PICP, and ICTP were measured in November to early December, and training and veterinary records monitored for the next 10 months. OCa and ICTP were significantly higher in horses that subsequently developed DMD (horses with DMD were defined as having an episode where clinical signs of DMD were sufficiently severe for a horse to miss 5 consecutive days of training). A multivariable logistic regression model indicated that horses with ICTP concentrations above 12,365 mcg/L and older than 20.5 months are 2.6 times more likely to develop DMD.

Bone Biomarkers and Osteochondrosis

Several studies have used biomarkers to identify young growing horses which have, or are at risk of, developing developmental orthopedic disease (DOD), osteochondrosis in particular. Osteochondrosis is associated with changes in bone as well as cartilage⁷⁰ and so it is appropriate to study both bone and cartilage biomarkers in the context of this condition. A small cross-sectional study demonstrated that ICTP concentrations were elevated in DOD, indicating that this disease is associated with increased bone resorption.⁷¹ However, in a study of Hanoverian foals there was no relationship between bone biomarker concentrations (OCa, ICTP, and PICP) and predisposition

to develop osteochondrosis,⁵⁶ although this study did not grade the severity of osteochondrosis. In contrast, there was a relationship between OCa concentrations and severity of osteochondrosis at 5 months in Dutch Warmblood foals.⁷² There was also a significant correlation between OCa concentrations at 2 weeks of age and the number of osteochondrosis lesions detected radiologically at 5.5 and 11 months,³⁸ although there was no significant relationship between CTX-I and radiological status. OCa concentration at 2 weeks of age was also significantly related to necropsy score in hindlimb joints. Further studies in larger populations are required to confirm whether OCa, together with specific cartilage biomarkers, provide a reliable clinical tool for identifying young horses at risk of developing osteochondrosis.

Bone Biomarkers and Osteoarthritis

A substantial amount of research has been directed at the value of biomarkers for assessing cartilage and bone anabolism and catabolism in equine OA.⁷³ The relationship between biomarkers of bone degradation and synthesis is reviewed because subchondral bone plays an important role in the pathogenesis of traumatic joint disease.⁷⁴

BALP is a potentially useful marker for analyzing changes in subchondral bone in equine OA. ALP activity in subchondral bone is increased in equine osteochondrosis.²³ In a cross-sectional study of OA, synovial fluid concentrations of BALP were significantly correlated with levels of two cartilage biomarkers and the degree of joint damage identified by arthroscopy.⁷⁵ In TB racehorses with osteochondral injuries in the fetlock joints, BALP concentrations in serum were significantly lower than in unaffected controls.²¹ BALP concentrations were significantly higher in synovial fluid from affected carpal joints compared with normal joints. Concentrations of BALP in serum with less than 30 U/L and more than 22 U/L and a ratio of synovial fluid to serum BALP greater than 0.5 were predictive of osteochondral injury. OCa also reflects bone anabolism but was not useful in detecting early subchondral bone disease in exercised horses.⁷⁶ However, a later study by the same group used a range of serum biomarkers to differentiate joint pathology and exercise-induced changes; OCa concentrations did correlate with measures of pain and modified Mankin score.⁷⁷ More recently a large number of bone and cartilage biomarkers were measured in treadmill-exercised 2-year-olds with or without an experimentally induced OA lesion.⁷⁸ OCa and type I collagen degradation were increased in the synovial fluid of OA joints compared with exercise-alone joints. Serum OCa and type I collagen concentrations were also significantly higher in OA-affected horses. CTX-I was not useful for separating early experimentally induced OA from exercise alone. In contrast, in human OA, CTX-I had value as a marker of bone resorption.¹⁵

EFFECTS OF EXERCISE ON BONE BIOMARKERS

The responsiveness of bones to changes in mechanical load ensures that skeletal mass and architecture are sufficiently robust to prevent injury.⁷⁹ Bone biomarkers provide a potentially valuable tool for studying the effect of exercise on bone and thus could possibly be used to help identify those training regimens that are osteogenic compared with

those that may be harmful, if the effects of exercise and disease can be distinguished.⁷⁸ There are conflicting results on the effects of exercise on bone biomarkers in horses. It was suggested that a higher OCa:ICTP ratio in Warmblood horses compared with draft horses may reflect a positive modeling response in horses having regular daily work.²⁶ Increased PICP, ICTP, and BALP concentrations have been found in treadmill-exercised 2-year-old female TBs compared with unexercised controls,⁸⁰ perhaps reflecting increased remodeling from accumulated fatigue damage associated with 18 months of training on a hard surface. In contrast, a follow-up study showed that a much shorter period of training, which increased bone mineral density in the exercised group, was associated with decreased ICTP and OCa concentrations.⁸¹ A decrease in OCa was also observed when Quarter Horses commenced race training,⁸² and two other studies showed lower OCa concentrations at the end of a training period.^{83,84} In TBs in commercial race training there were decreased OCa concentrations as the intensity of work increased.⁶⁶ However, OCa levels increased in young Standardbreds after 6 months of race training.⁸⁵ In an experimental study designed specifically to discriminate between changes in cartilage and bone biomarkers with treadmill exercise and OA, synovial fluid and serum OCa and collagen I concentrations increased.⁷⁸ There was no clear pattern of change with CTX-I, whereas a previous study in Warmblood foals found higher CTX-I levels in foals trained for the first 5 months of life compared with those raised at pasture or in a box stall.⁵⁷

Changes in bone turnover may not be revealed using bone biomarkers because a training regimen is not sufficiently osteogenic. For example, lunging yearling Quarter Horses had no effect on OCa levels⁸⁶; no change on DPD or OCa concentrations was observed when previously stabled Arabian horses returned to training.⁴⁵

Although increased loading has anabolic effects on bone, disuse is catabolic and leads to increased resorption. Bone biomarkers have shown that a period of immobility may predispose horses to injury. When Arabian yearlings were confined to a stable, serum concentrations of the resorption marker DPD increased, whereas levels of the formation marker OCa decreased compared with levels in controls kept at pasture. There was a decrease in bone mineral content.⁴⁵ A decrease in OCa levels after transfer of foals from pasture to winter stabling has been described.⁵⁴ However, age and/or a horse's previous exercise history may influence the effect of immobility on bone turnover because OCa and Hyp levels were unchanged during a 12-week period of stall confinement in older Arabian horses despite a decrease in bone mineral content.⁴²

MONITORING RESPONSES TO THERAPY

To date, monitoring responses to therapy has proved to be one of the most valuable applications of bone biomarkers in human medicine.¹⁶ The newer bone resorption markers in particular provide a very sensitive measure of the effects of antiresorptive agents on bone turnover. In osteoporotic women, type I collagen N-terminal telopeptide (NTX) and CTX decrease within months of bisphosphonate treatment.⁶⁴ There is already some evidence that in horses bone biomarkers may be useful for monitoring responses to therapy and also for assessing the potentially harmful

effects of drugs on the equine skeleton. For example, bone biomarkers have showed that corticosteroids have a negative effect on osteoblast activity, and in the long term this could lead to osteoporotic changes in bone.^{87,88} OCa levels have been found to be significantly decreased after intravenous, intramuscular, and oral administration of dexamethasone and triamcinolone acetonide.^{87,88} In contrast, levels did not decrease after intraarticular injection of methylprednisolone acetate, which suggests that this route of corticosteroid administration may not have long-term adverse effects on bone.⁸⁹ Serum BALP did not reflect decreased mineral apposition rate associated with phenylbutazone administration²⁰; however, this was a relatively short-term study, and in people changes in bone formation biomarkers may not occur for several months after treatment.⁵⁴ Bone marker levels were increased after growth hormone administration in horses and thus could be useful as indirect measures for detecting its abuse in racehorses.⁹⁰ More recently, CTX-I and BALP were measured in a study designed to test the effect of the bisphosphonate tiludronate on disuse osteoporosis induced by the application of a cast to the left forelimb.⁹¹ There was a transient, rapid decrease in CTX-I after tiludronate administration.

In my opinion the use of bone and cartilage markers to monitor the effects of treatment may be one of the most important applications for the markers in equine orthopedics, to provide an objective reflection of how treatment regimens influence catabolic and anabolic processes in bone.

In conclusion, bone biomarkers provide a relatively inexpensive, straightforward, and noninvasive method for studying changes in the activity of cells responsible for forming and resorbing bone. To the basic scientist bone biomarkers can contribute to understanding the cellular mechanisms that underlie normal and abnormal bone development and (re)modeling. To the clinical researcher bone biomarkers provide insight into disease pathogenesis and assist in developing prevention and treatment strategies for equine musculoskeletal diseases. The inherent biological variability of bone biomarkers means that they are unlikely to be appropriate for diagnosing bone disease with absolute certainty when measured on a single occasion. This notwithstanding, there is accumulating evidence that bone biomarkers are potentially useful in the clinical setting, particularly when measured longitudinally with other biomarkers and used alongside diagnostic imaging modalities. Future research needs to be directed at replicating results obtained from experimental and relatively small clinical studies in large multicenter studies. There needs to be greater understanding of how variables such as exercise, growth and intercurrent disease may influence bone biomarkers, and administrators of laboratories need to start developing cost-effective, reliable biomarker panels appropriate for different clinical scenarios. If work in this area continues to progress, in 10 to 15 years bone biomarkers will likely be part of an established repertoire of tools that equine clinicians will have at their disposal for identifying horses at risk for developing disease, for achieving early diagnosis of bone and/or joint diseases, and for monitoring disease and repair progression. Inevitably this will lead to a reduction in the prevalence of lameness and wastage in equine athletes, racehorses in particular, an outcome which remains a priority and a major challenge.

Chapter 102

The Bucked-Shin Complex

ETIOLOGY, PATHOGENESIS, AND CONSERVATIVE MANAGEMENT

David M. Nunamaker

Conditions of fatigue failure of bone and inadequacy of bone modeling and remodeling of the third metacarpal bone (McIII) in the racehorse are part of a condition known as *bucked shins* or *dorsal metacarpal disease*.^{1,2} Bucked shins start in young healthy racehorses, usually Thoroughbreds (TBs) and Quarter Horses, but occasionally Standardbreds (STBs), that undergo intense training for racing, usually as 2-year-olds, while the skeleton is still immature and in the growth phase (Figure 102-1, A). The true incidence of

References
on page
1340

bucked shins is unknown and may vary geographically, but reports range from 30% to 90%. A North American questionnaire cited an incidence of 70%.¹ Stress fractures (dorsal cortical or saucer fractures) usually occur some months after initial signs of bucked shins and may be a potentially life-threatening injury if a horse is raced or exercised at speed (see Figure 102-1, B). The diagnosis of bucked shins is easy and often made by the trainer or owner. The history of sudden tenderness or soreness of the left McIII (in North America) or both the McIIIs after high-speed work or the first race, or soreness developing the day after, are cardinal signs of early bucked shins. Horses with severe disease manifest acute lameness and extreme sensitivity to palpation of the dorsal cortex of the McIII and are unwilling to train or race. All gradations of pain or disability may be seen. Swelling and tenderness may suggest new bone proliferation. Radiology is helpful to determine the amount of periosteal new bone formation, which determines prognosis. Large accumulations of periosteal new bone on the dorsal or dorsomedial surface of the McIII suggest a serious imbalance between exercise and bone fatigue and may portend actual stress fractures that will be seen on the dorsolateral aspect of the McIII some months later.

RESEARCH FINDINGS

An understanding of the etiology, pathomechanics, and pathogenesis of bucked shins in the TB is helpful in determining prevention and/or treatment modalities and training regimens. It was formerly suggested that bucked shins resulted from microfractures on the dorsal aspect of the McIII, caused by high-speed exercise. However, microfractures should heal without periosteal callus, which does not fit with the clinical observation of extensive periosteal new bone on the dorsomedial aspect of the McIII. Work in our laboratory led us to propose a different cause of bucked shins³ and an exercise program that significantly reduces the incidence of bucked shins and may help to eliminate catastrophic stress fractures. The following summarizes our investigations.

Geometric Properties of the Third Metacarpal Bone: Comparison of Thoroughbreds and Standardbreds

The McIIIs of TBs and STBs of known age were examined, and comparisons were made between breeds of a particular age group and among the age groups of a particular breed. The second moments of area relate to bending stiffness in dorsopalmar and mediolateral directions and were used to determine the minimum and maximum principal moments of inertia (I_{\min} and I_{\max}). The most significant changes in the bone occurred at the midsections between the ages of 1 and 2 years, but continued change occurred until age 3 or 4 years. I_{\min} was smaller in the yearling TBs but larger in the adult TBs compared with STBs. During the first 2 to 4 years of life, I_{\min} changed to a greater extent in TBs.⁴

In Vitro Comparison of Local Fatigue Failure of the Third Metacarpal Bone

Dumbbell-shaped specimens machined from adult McIIIs from TBs and STBs were tested in fully reversed cyclic bending experiments using a constant-strain rotating

Fig. 102-1 • **A**, Dorsolateral-palmaromedial oblique radiographic image of a third metacarpal bone (McIII). Periosteal new bone formation (arrows) over the dorsomedial aspect of the McIII is evidence of bucked shins. **B**, Lateromedial radiographic image of the metacarpal region. This dorsal cortical fracture of the dorsolateral aspect of the McIII represents a common type of fatigue (stress) fracture (arrows) that usually occurs months after an episode of bucked shins.

Fig. 102-2 • In vitro fatigue data are plotted for the adult Thoroughbred (TB) and Standardbred. The regression line shows where the third metacarpal bone (McIII) will fail from repeated cycles. Superimposition of the strain levels of young TBs shows that 41,822 cycles would result in fatigue failure. The superimposition of an older TB shows that more than a million cycles would be needed before bone failure.

cantilever model that measured load decrement. All tests were performed at 40 Hz and continued until the specimen broke or had a 30% loss of stiffness. Three different offsets were used to establish nominal strains of 7500, 6000, or 4500 microstrain in the specimens.

Data were analyzed using a power regression model for each horse and for each breed. Statistical differences were not found among the curves for individual horses of the same breed or for the curves between breeds. Pooled data then were used to describe fatigue characteristics of cortical specimens of the McIIIs from TBs and STBs of various ages, subjected fully to reversed cyclic loading (Figure 102-2).⁵ The bone from young horses was much more susceptible to fatigue failure.

Because the in vitro fatigue was similar in TBs and STBs, other factors appeared to be important in the pathogenesis of fatigue failure of bone in the TB. This, together with the different inertial properties noted in STBs and TBs, led to the hypothesis that differences in training regimens or racing speeds between breeds might influence the incidence of disease.

Third Metacarpal Bone Stiffness Measurements

Whole bone stiffness measurements were made from horses of 2 months to 28 years of age using an Instron testing machine (Instron, Canton, Massachusetts, United States) and a nondestructive three-point dorsopalmar bending test. The bones showed general increases in stiffness until they reached a plateau at about 6 years of age.

The material included the McIIIs from 12 2-year-old TBs, three of which had bucked shins. These three horses had differences in stiffness between the left and right McIIIs of 16% to 27%, respectively, whereas other trained or control 2-year-olds had considerably smaller left-right differences.⁶

In Vivo Strain Measurements:

Relationship to Exercise

Bone strain in the McIII was measured in horses of varying ages, training at or near racing speed, by placing a rosette

strain gauge on the dorsolateral aspect of the McIII and recording using telemetry.⁷ The mean peak compressive strain in four horses 2 years of age was -4841 ± 572 microstrain, compared with -3317 in a horse 12 years of age. One 2-year-old developed bucked shins, and its strain measurements were about 6 standard deviations greater than in the other three.

After acquiring in vivo strain data, we correlated these data with in vitro fatigue data previously generated by determining the average number of cycles that a young TB would gallop in training before the onset of bucked shins. The training records of six 2-year-old TBs that developed bucked shins were analyzed to determine the total distance worked before the onset of bucked shins. Stride length at canter, gallop, and racing speed was measured in a group of TBs to determine the number of strides (cycles) per mile. The total number of gait cycles was estimated based on the distances covered at a canter, at a gallop, and at work. The six horses were trained in these gaits for 10,000 to 12,000 cycles per month and developed bucked shins at 35,284 to 53,299 training cycles. These data were compared with the in vitro data described previously and showed good correlation (see Figure 102-2).

Changing from the trot to the gallop changed the principal strain direction by more than 40 degrees on the dorsolateral surface of the McIII. Although trotting horses showed tensile strains in the long axis of the bone on the dorsal or dorsolateral surface, at racing speeds this same surface of the bone showed compressive strains.⁸

Relationship of Exercise to Bone Fatigue

With the understanding that slow-speed gaits produced tensile strains on the dorsal surface of the McIII, whereas high-speed exercise induced compressive strains, a study was undertaken to determine the effects of different training regimens and track surfaces on the modeling and remodeling of the McIII in TBs.

Eight untrained 2-year-old TBs were divided into four groups of two horses each. Classical training methods were used for the horses in groups I and II. Group I horses trained on a dirt track. Group II horses trained on a wood chip track. Group III horses (control group) were not trained, but they were allowed free exercise in a large pasture. Group IV horses were trained using a modified classical training program on a dirt track.

The classical training program consisted of daily gallops (approximately 18-second furlongs or 11.2 m/sec) of 1 to 2 miles per day (1.6 to 3.2 km), followed by shorter workouts or breezes at racing speed (approximately 14-second furlongs or 14.4 m/sec) once every 7 to 10 days that increased in distance from 2 to 6 furlongs (0.4 to 1.2 km) progressively over the course of the study. The modified classical training method used similar daily gallops, but the frequency of the high-speed workouts increased to three per week, and distances increased progressively from 1 to 4 furlongs (0.2 to 0.8 km). After 5 months the McIIIs were harvested from all horses. Microradiographs of bone sections were made to determine the extent of the remodeling activity (Figure 102-3). Bone modeling on the periosteal and endosteal surfaces of the McIII changed the cross-sectional geometry differently among the experimental groups. Classically trained horses (groups I and II) responded with appositional new bone formation on the

Fig. 102-3 • Fifty-percent length cross-sections of the third metacarpal bone were used to make these microradiographs. Individual photographs were taken with cross-sections magnified four times, and giant montages (approximately 50 × 70 cm) were constructed to be able to evaluate individual haversian systems of each individual bone of each horse. Lateral is to the left. **A**, Group I horses: classically trained on a dirt track. **B**, Group II horses: classically trained on a wood chip track. **C**, Group III horses: controls. **D**, Group IV horses: modified training on a dirt track. Changes in modeling, remodeling, and shape can be seen easily by comparing different groups. Group II horses appear to be earlier in the remodeling cycle than are group I horses, which already have remodeled in the medial and lateral cortices. All specimens are from the left forelimb, and increased new bone formation is seen on the medial surface of the classically trained horses (groups I and II). Modified training (group IV) and the control horses (group III) do not show this change. The lack of haversian remodeling in the dorsal-dorsolateral cortex of the classically trained horses in groups I and II is notable. In this area catastrophic stress fractures occur in racehorses.

dorsomedial periosteal surface, giving the impression that the medullary cavity, although reduced in diameter, was displaced laterally. Horses in the modified training group (group IV) had bone deposition dorsally and a slightly larger medullary cavity that was not displaced laterally. Control horses (group III) had new bone formation on the medial, lateral, and dorsal surfaces. The medullary cavity remained large and centrally placed. Examination of the McIII inertial properties showed that I_{min} in groups I, II, and III was similar, but the I_{min} of group IV horses was greater and was similar to the I_{min} previously reported for mature racehorses.

Microradiographic sections from the middiaphysis of the McIII showed that bone remodeling occurred only medially and laterally in groups I and II. Filling of secondary haversian systems with new bone was most complete in group I specimens, indicating that the remodeling process was advanced further in horses exercised on a harder surface. A distinct lack of remodeling activity was apparent in the dorsal and dorsolateral regions in groups I and II. Horses in groups III and IV showed extensive remodeling throughout the cortex, including remodeling in the dorsal and dorsolateral aspects.

These data suggested that in horses training on a hard surface, bone remodeling occurred at a faster rate than in horses training on a compliant (wood chip) surface. Previous studies showed that classically trained horses on a hard surface have a higher incidence of bucked shins than do horses trained on a more compliant surface. One horse in group I developed bucked shins during the training period. Inertial properties (I_{min}) of the McIII in the dorsopalmar direction were no different in horses trained on a hard or soft track. Horses in group IV had a significant change in I_{min} of the dorsal cortex of the McIII, similar to that seen in adult racehorses evaluated previously that were no longer at risk for developing bucked shins.³ This supported the concept that exercise could be designed to optimize the shape and modeling or remodeling status of the McIII and thus reduce the incidence of bucked shins.⁹

Exercise Programs Designed to Decrease the Incidence of Fatigue Failure

To determine the efficacy of an adapted training program in decreasing the incidence of bucked shins, a prospective and retrospective study was performed using work training

data from five commercial training stables. Two of the stables (2 and 5) were already using our modified classical training program, and the others (1, 3, and 4) were training in a classical manner. Horses in stables 1, 2, and 4 were trained on a commercial racetrack, whereas those in stables 3 and 5 were trained on private farm training tracks. All horses in the study were TBs, 2 years of age, and starting training for the first time and were followed for 1 year. Data collection stopped if horses developed bucked shins, were sold, or stopped training because of another event not related to bucked shins. The study included 11 years of training data from 226 2-year-olds. Fifty-six of the 226 horses developed bucked shins, and 170 horses completed the observation period or were sold.

Regression analysis and survival analysis techniques were used to explore the data. Horses in stable 2 had the best survival, and those in stables 1 and 4 the worst, and evaluation of data suggested that relationships between galloping and breezing were important. Horses in stable 2 had the highest breezing rate and the lowest incidence of bucked shins, whereas those in stables 1 and 4 had the highest galloping rates and the highest incidence of bucked shins.

Gallop increased the likelihood of bucked shins by 36.4%, whereas breezing short distances was protective, reducing the likelihood of bucked shins by 98.6%.¹⁰ It is important to note that long-distance breeze rates are detrimental.¹¹ The winter of 1994 brought severe ice storms to the northeast. Horses in stable 2 could not be trained using the modified program and instead were trained using the standard classical program. An unintentional crossover design was created, and 62% of the horses trained that year developed bucked shins. When 1994 data are not used, only 9.3% of horses developed bucked shins.

In Vitro Bone Testing

In vitro compression testing of cylindrical specimens obtained from the McIII of 16 horses (139 specimens) in four different training regimens that included no training were tested to failure to determine differences in modulus and strength. These specimens included three horses that developed bucked shins. Because these in vitro studies showed no statistical differences in the material properties of bones with different training regimens, a change in material properties of bone is not a factor in the etiology or pathogenesis of bucked shins. From this study and previous ones carried out in our laboratory, it can be hypothesized that early in a TB's racing career the McIII experiences extreme strain conditions. These strains cause bone apposition on the dorsal periosteal surface of the McIII in an attempt to lessen the strains. This causes a change in the geometric properties (section properties) but not the material properties of the existing bone.

DISCUSSION

Two decades of evolutionary experiments and clinical observations based on an initial observation of a significant difference in the incidence of fatigue fractures between TB and STB racehorses have led to a natural model for fatigue failure of bone.^{11,12} We can now compare in vitro and in vivo fatigue behavior and observe bone adaptation with different exercise regimens. Adaptive exercise was shown

to change the geometric properties of the McIII without changing the material properties, to influence bone modeling and remodeling, and to reduce the incidence of bucked shins and catastrophic fatigue failure of the McIII in the TB.¹³

Comparisons of TBs and STBs show major changes in inertial properties of the McIII resulting from growth and superimposed training. Comparisons of young TBs that are susceptible to fatigue failure, with older, resistant horses suggest that changes in bone inertial properties are an important factor affecting the incidence of bucked shins. Large McIII I_{min} values reflect probable increases in the McIII stiffness in the dorsopalmar direction and thus reduced peak strain during high-speed exercise. The inertial properties of the proximal aspect of the tibia were shown to predict development of fatigue fractures in military recruits,^{14,15} just as the inertial property measurement of the McIII of 5-year-old TBs shows that these horses are no longer at risk for bucked shins.⁴

In vivo strain measurements of the McIII demonstrated higher peak strains under physiological loading than ever had been reported previously in any species. Although in vitro test conditions differed from the in vivo loading, both involved significant bending components that can be expected to produce accumulated fatigue failure in bone. Superimposition of the in vivo strains reported for the young and older horses at racing speed produced a striking predictive relationship for risk of developing bucked shins (see Figure 102-2).

Large surface strains, measured in vivo at high speeds on the dorsolateral aspect of the McIII in young TBs in training, contrast dramatically with the smaller strains measured in adults that have raced successfully. Strains, under a given load regimen, measured on the surface of bone relate to the modulus and inertial properties (section modulus) of the bone. Because inertial properties were shown to increase with age, and bone strains during high-speed exercise were shown to decrease in older horses, the hypothesis was that changes in bone inertial properties and modulus serve to lower the peak bone strains as a young racehorse matures. However, training regimens possibly can outpace adaptive response. In fact, we observed that a certain percentage of young horses actually increased the McIII surface strains after several months of training. Whole bone stiffness measurements showed right-to-left differences of up to 27% in horses in training, whereas no right-to-left difference was found in the nontrained control horses. Because bucked shins occur bilaterally but sequentially in TBs, usually on the left side before the right, the developmental stiffness changes in limbs possibly are not synchronized but may respond to the predominance of the left lead used by the horse in its racing gait as the horse works in a counterclockwise direction. Maximal strains at exercise and bone stiffness parameters probably change with time and may be declining on one side, while increasing on the other. Increasing bone strain measured at high speed during training, as seen in four of seven TBs, suggested rapid bone stiffness changes in vivo from exercise. Because we now believe that material properties of the bone do not change dramatically during this phase of training, this means that the horses must be providing larger forces on the bone (running faster or applying increased muscular input into the bones).

If Wolff's law is applied strictly, it follows that a bone that adapts to a particular peak tensile strain may not be prepared adequately to resist far larger peak compressive strains in the same location. Hence training adapts bone to training, and training that mimics racing adapts bone to racing.

An *in vitro* fatigue study of equine McIIIs showed a difference in fatigue resistance to bending loads in different anatomical quadrants. Bone that was loaded in bending around the physiological bending axis had greater fatigue resistance than bone bent at 90 degrees to this axis.¹⁶

We hypothesized that to adapt adequately for racing, the McIII should be exposed during training to strains of the actual magnitude and direction experienced during racing. Furthermore, the high incidence of bucked shins in TBs suggested that loading to produce such peak strains and concomitant adaptive remodeling did not occur in a large number of TBs in classical training programs before racing.

Previous *in vivo* studies using a functionally isolated rooster ulna, have shown that low numbers of loading cycles (four per day) were adequate to maintain bone mass. Thirty-six cycles were enough to stimulate bone formation.¹⁷ The resulting periosteal new bone formation is the same type of bone reaction observed in the TB McIII with fatigue injury.

With these observations taken into account, an exercise (training) regimen was developed that modestly increased the small numbers of high-load cycles using peak load magnitudes and directions that were seen during racing. Increasing the number of short-distance workouts (breezes) from once every 7 to 10 days, as occurs with classical training programs, to three per week produced large changes in modeling, remodeling, and inertial property measurements of the McIII. Classical training produced little progressive change in the inertial properties of the McIII, whereas the new modified training program showed inertial property development that equaled or surpassed that observed in established older successful TBs, those horses apparently no longer susceptible to bucked shins.³

The idea of using exercise to produce adaptive bony remodeling is not new. Woo and colleagues¹⁸ showed that 12 months of exercise in young pigs produced dramatic changes in the femur, increasing cross-sectional area by 23% and inertial properties (I_{min}) by 27%, without intrinsic bone property changes.¹⁸ Milgrom and co-workers¹⁹ looked for exercise that can adapt bone and showed that playing basketball for 2 years or more was protective in reducing the incidence of bone fatigue failure in military recruits.

In the 11-year longitudinal study, we proved that adaptive exercise could be used to reduce the incidence of bucked shins. The relative incidence of bucked shins in classically trained TBs is probably higher than we found. The mean time taken for horses to develop bucked shins was about 25 days shorter than the mean time to loss for other reasons. Bucked shins developed in most horses by 200 days in training. We would not expect horses in the modified training program to experience additional fatigue fractures after the observation period, because the McIII should resemble more closely that of adult, nonsusceptible racehorses.

Adaptive exercise changed the geometric parameters of a specific bone in a way that would be expected to reduce

fatigue damage while significantly reducing the incidence of bucked shins. This correlation, although not explicit proof of the interrelationship between the factors measured, is convincing.

In addition, approximately 10% of the catastrophic breakdown injuries involving the skeleton of TB racehorses are complete fractures of the McIII. These injuries are direct sequelae to fatigue fractures of the dorsolateral aspect of the McIII that are often seen several months after horses develop bucked shins. Theoretically, if bucked shins could be prevented there would be an immediate 10% decrease in the incidence of these catastrophic fractures and thereby a decrease in racing fatalities.

TRAINING TO PREVENT BUCKED SHINS

A training program was developed to limit the incidence of bucked shins and can be modified by trainers to suit their situations.^{12,20}

The principles of this training program are the following:

1. Bone changes its shape and structure based on its use (Wolff's law). It therefore follows that training adapts bone to training, racing adapts bone to racing, and training that mimics racing adapts bone to racing.
2. Short, high-speed workouts are introduced into the training program early and often (two per week) to introduce bone to the forces it will experience during racing.
3. Galloping is done in moderation (1 mile/day, 6 days/week). Long gallops result in high mileage that may induce high-strain cyclic fatigue of bone.
4. Jogging is used for warm-up only and is not used to increase a horse's level of fitness, because jogging induces tension on the dorsal surface of the McIII. Once bone adapts to racing (6 to 8 months), this training program is no longer needed, because bone will not regress into its previous shape and architecture. Any successful program can then be instituted.

These principles were developed based on experimental studies that showed that at slow gaits the dorsal surface of the McIII is under tension and at high speed is bending to produce compression. Structurally, materials are designed differently to support tension or compression. Think how strong a rope is in tension and how useless it is in supporting loads in compression. Short, high-speed exercise exposes the bone to compression on its dorsal surface and introduces the bone to the loads expected during a race. Experimental studies showed that this sort of training regimen changed the cross-section of the McIII to the adult racing shape within 6 months.

Long, low-speed jogging adapts the bone only to jogging, creating tension on the dorsal surface of the McIII. In stable 2 in the icy winter of 1994 the horses were jogged for 30 days, without any high-speed exercise, and then resumed the exercise program. The incidence of bucked shins increased fivefold compared with previous years and returned to normal the following year. Although training is not a cookbook recipe for success, the fundamentals of the program are described here with an actual schedule.¹²

The schedule assumes that the young horse is broken to ride in the fall and is able to gallop 1 mile (18- to

20-second furlongs) by the end of December. The training program starts in January and can be broken into three stages. The principle involved is that the horse's bones need to see the strain environment of racing as soon as possible so that bone modeling and remodeling can begin in a timely manner. The training program is 6 days a week with Sundays off. The horses walk to and from the racetrack. On the track the horse walks $\frac{1}{2}$ mile and jogs $\frac{1}{2}$ mile to warm up. The horse then gallops 1 mile.

Stage 1—Using the strategy just described, the horse will finish the gallops two times a week with a $\frac{1}{8}$ -mile open gallop in 15 seconds. This speed work is done on Tuesdays and Saturdays. This speed and distance of the open gallop is repeated 10 times (5 weeks).

Stage 2—After 5 weeks of stage 1 gallops, the horse moves up in distance so that two times a week (Tuesday and Saturday) the horse will finish its gallop with $\frac{1}{4}$ mile in 30 seconds (15-second furlongs). This speed work is repeated 10 times, which takes up the next 5 weeks. All open gallops in stage 1 and stage 2 are at the end of the gallop and are included in the 1-mile gallop.

Stage 3—After the completion of stage 2, the horse continues its training using speed work once a week (Saturday), breezing $\frac{1}{4}$ mile in approximately 26 seconds (13-second furlongs). This is repeated four times (4 weeks). In stage 3 the daily gallops are extended to $1\frac{1}{4}$ miles twice a week. After the fourth week the $\frac{1}{4}$ -mile breeze is continued with a strong "gallop out" for an additional furlong. This makes the 3-furlong total about 40 seconds. This is done for an additional 3 weeks, giving stage 3 a total time of 7 weeks.

After stage 3, the McIII shape and architecture are effectively established for the longer high-speed workouts necessary for racing. The horse can now go on to 4- to 6-furlong workouts as needed to further develop other body systems to complete fitness for racing. The total time of this initial training program is 119 to 147 days, depending on the availability of a race for the horse. This does not include any downtime for sickness or injury. Gate work is started early and often in this program. The horses are introduced to the gate in January as the program starts. All young horses are turned out in a small paddock for 1 to $1\frac{1}{2}$ hours of exercise before daily training. This training program has shown no increase in the injury rate of young horses. An excellent byproduct of this training program is the mental development of these 2-year-olds. Because of the very relaxed atmosphere of walking to and from the racetrack, these horses exhibit no anxiety about work. For this training program to work, the rider cannot be in a hurry to get back to the barn and on the next horse. The 2-year-olds are not anxious about speed work because it has been in the weekly schedule since the beginning of training. All the horses walk back to the barn. Walking is a great exercise that does not seem to negatively influence bone modeling or remodeling. The schedule described here for training to negate bucked shins is just that—a schedule. An understanding of the principles behind this training regimen is important. Training programs that take advantage of this information can be developed that will meet an individual horse's needs.

Horses that develop respiratory disease during training and are off for 10 days or more are backed up about 10 days in the training program. Shin sore horses are treated for soreness with phenylbutazone and ice water and are walked until soreness is gone. These horses then get put in an abbreviated program in which the breezing distances and galloping distances are cut in half. These horses are usually coming from a classical training program, in which bucked shins is a common occurrence. When presented with these horses (often from a 2-year-old in training sale), one is far better off putting them into this bone-conditioning program initially rather than going on with them and hoping that they do not develop bucked shins, as they invariably do. These horses take far longer to get to the first race. Sore horses should be individually evaluated based on clinical and radiological signs. In most horses that develop early shin soreness the training program can be modified and the horse can continue training. A short rest period with handwalking, the administration of phenylbutazone, and the application of ice water can get most horses back into training rather quickly.

Although bucked shins are commonly accepted by veterinarians, trainers, and owners as a normal training event in young TB racehorses, with estimated losses to the industry of \$10,000,000 per year in lost training and racing days, they are far more important than that! Horses with bucked shins are at increased risk to develop dorsal cortical fractures of the McIII and then may have catastrophic failure of the McIII during racing. Horses without bucked shins are at very low risk to develop these fractures.

Horses with bucked shins can be trained using this program, provided that the horse is sound and periosteal new bone formation is not substantial. The secret is to decrease the horse's galloping distance (cut it in half) and add short high-speed workouts. For example, if a horse usually gallops $1\frac{1}{2}$ miles/day, reduce the distance to $\frac{3}{4}$ mile/day and introduce short workouts twice weekly. We usually back the horse up about 1 month in its exercise program and get the high-speed workouts started over short distances. If horses are sore or lame, training is stopped and cold therapy and administration of nonsteroidal antiinflammatory drugs (NSAIDs) are begun. Once sound, horses are returned to training. In some horses NSAIDs may need to be administered for chronic soreness, but horses with frank lameness should be allowed to rest until sound.

If a horse's training schedule is interrupted by an unrelated lameness or upper respiratory tract disease, remodeling that starts with bone resorption is sudden. When the primary problem resolves, if horses are returned to training at a level similar to that before rest but the McIII porosity is increased, the horse is at risk for bucked shins. Therefore if a horse is out of the exercise program for 10 days or more, the horse should be backed up in its training schedule to minimize the risk of bucked shins when it restarts training.

With proper training the incidence of bucked shins can be reduced dramatically (almost eliminated). This can be accomplished without increasing the training time or risking added injury. The added benefit of this program is the concurrent absence of dorsal cortical fractures of the McIII in horses without previous bucked shins.

Fig. 102-4 • Lateromedial radiographic image of a third metacarpal bone (McIII) of a 4-year-old Thoroughbred. Dorsal is to the left. Typical dorsal cortical stress fracture of the third metacarpal bone, cortical thickening of the McIII, and numerous oblique fracture lines are present. This horse is a candidate for drilling or screw placement.

■ STRESS FRACTURES OF THE THIRD METACARPAL BONE: SURGICAL MANAGEMENT

Alan J. Ruggles

Most stress fractures of the McIII occur on the dorsolateral aspect of the left forelimb but may be bilateral ([Figure 102-4](#)). Treatment options include controlled exercise (see page 958), screw placement in the dorsal cortex, and cortical drilling around the fracture line. Recently extracorporeal shock wave therapy has been used with apparent early success (Editors, see Chapter 96). The placement of a screw does not result in interfragmentary compression, but it may have a local effect on bone modeling and remodeling. Cortical drilling is thought to improve vascularization and new bone formation at the fracture line.¹ Advantages of cortical drilling alone are that a second surgery is not necessary to remove the screw, and in some horses this procedure can be performed with the horse in a standing position, obviating the need for general anesthesia. However, drill breakage in a standing horse is a risk and, if the bit piece is not retrieved, may lead to chronic lameness. Clinical reports indicate that the use of cortical drilling and screw placement has a lower rate of fracture recurrence than cortical drilling alone. Success rates were 97% and 85%, respectively.^{2,3} I use the combination technique.

Horses with radiological evidence of substantial endosteal or periosteal healing often heal satisfactorily without surgical intervention. Horses with severe fractures that are in multiple locations, or spiral around the bone, have a risk of catastrophic failure on recovery from general anesthesia

Fig. 102-5 • Lateromedial radiographic image of the third metacarpal bone (McIII) of a 2-year-old Thoroughbred. Dorsal is to the left. There is a severe, dorsal cortical fracture of the McIII. Conservative management in horses with severe fractures is recommended. This fracture is saucer-shaped in appearance and could propagate during recovery from general anesthesia.

and usually are treated conservatively ([Figure 102-5](#)). To my knowledge no objective reports of conservative management of dorsal cortical stress fractures exist. In my experience conservative management is less reliable than surgical treatment and does not result in a reduction in training days missed. In addition, I have experienced a higher rate of recurrent fracture, or failure of fracture to heal, with conservative compared with surgical management.

SURGICAL PROCEDURE

The horse is positioned in lateral recumbency under general anesthesia with the affected limb uppermost. Both limbs can be operated on from this position. The periosteal new bone usually can be felt through the skin, and a 6- to 8-cm vertical incision is made over the fracture, usually between the common and lateral digital extensor tendons. Radiographic examination is used if necessary. The periosteum should not be elevated. A sharp 2.5-mm drill bit is used to drill a thread hole for a 3.5-mm screw perpendicular to the fracture line. Screws are placed as positional screws rather than in lag fashion. Only the dorsal cortex is drilled. Overdrilling may result in impact on the palmar cortex and instrument breakage. During or after screw placement, radiological examination is necessary to determine proper screw placement. The screw is placed after countersinking, tapping, and measuring to determine appropriate screw length. Usually a single screw is used, but occasionally several screws are used for a long fracture. Five or six uncortical drill holes approximately 1 cm apart are made using a 2.5-mm drill bit in the region of the fracture, before routine closure and bandaging of the limb.

If dorsal cortical drilling alone is performed with a horse in the standing position, under sedation and perineural analgesia, a 3.2-mm drill bit is used to decrease

the risk of drill breakage if the horse moves during the procedure.

POSTOPERATIVE TREATMENT

Four weeks of stall rest with handwalking followed by 4 weeks of small paddock turnout, continued handwalking, or swimming are recommended. Screw removal is performed with the horse standing at 8 weeks, based on fracture healing. Return to light jogging can occur 2 weeks after screw removal, but more intense training should not start until at least 16

weeks after surgery and should be based on lack of clinical signs of lameness and radiological signs of healing.

PROGNOSIS

Prognosis is considered good, with 85% to 97% of horses returning to racing.^{2,3} Recurrence of fracture is more common after cortical drilling alone, compared with the combination of cortical drilling and screw placement. Catastrophic failure has occurred after cortical drilling alone but not with the combined technique.

Chapter 103

On-the-Track Catastrophes in the Thoroughbred Racehorse

W. Theodore Hill

Horses in racing and high-intensity training are subject to a variety of musculoskeletal injuries. For North American racing the overall incidence of musculoskeletal injuries ranges from 3.3 to 7.3 per 1000 starts, depending on variables such as reporting criteria and degree of follow-up. A much closer range of 1.1 to 1.8 injuries per 1000 starts is reported for horses with catastrophic injuries resulting in euthanasia.¹ Catastrophic or fatal injuries are documented more reliably and are considerably less subject to bias or misinterpretation by the reporter. The rates for training injuries may be somewhat higher, although accurate acquisition and evaluation of these data is more difficult. To date, limited information is available regarding training injuries.^{1,2} Several factors cannot be controlled during training, making information obtained inaccurate and incomplete. The absence of a veterinary observer during most training sessions allows many lameness incidents to go unreported. Often only injuries requiring an ambulance come to the attention of a track veterinarian. During training, no standard exists for soundness, medication use, and exercise rider skill. Differences between training injuries and racing injuries are documented when they exist. In July 2008, the Jockey Club launched the Equine Injury Database (EID) to provide the racing industry with a national database for racing and training injuries. The purpose of the EID is to collect comprehensive data to serve as a resource for epidemiological study to improve safety and prevent injuries. Additional information on the EID can be found at www.incompasssolutions.com.

Information about racing injuries presented in this chapter applies to racing worldwide. However, discussions of the regulatory veterinarian primarily refer to racing in the United States.

REGULATORY VETERINARIAN

The official veterinarian and staff members at a U.S. Thoroughbred racetrack have many duties. The primary responsibility is monitoring the soundness of horses during racing and, to some degree, training. This task is accomplished by an efficient prerace inspection and observation of all horses before, during, and after a race. After the horse has been identified, a visual assessment is made of the overall condition and attitude, and vital parameters are assessed. Ideally the temperature, pulse, and respiratory rates are recorded, and the eyes and mouth are examined closely. The mouth should be free of any inflammation or lacerations, which the bit would aggravate, possibly causing control difficulties for the rider. The forelimbs and hindlimbs are palpated, and attention is paid to the type of shoes worn and the condition of the feet. When bar shoes, aluminum pads, or quarter crack patches are noted, closer inspection of the foot is indicated. A palmar digital neurectomy is permitted in most jurisdictions. The clinician must always check for a neurectomy to ensure compliance with the rules. Usually a horse that has undergone neurectomy must be reported to the track veterinarian and its name conspicuously displayed for claiming races.

Any horse determined to be sick or unsound for racing is reported to the track stewards and withdrawn from the day's racing card. Only the stewards have the authority to officially scratch a horse, although in practice a track official rarely questions the veterinarian's recommendation. The veterinary department must function as an independent authority, and neither management nor anyone connected to a horse should interfere with the veterinarian's decisions.

Once withdrawn for a veterinary reason, a horse is usually placed on an ineligible list and requires further evaluation before being permitted to race again. Depending on the nature of the illness or lameness, the evaluation may involve only a quick check; if the condition is more serious, a monitored workout and thorough examination may be required. The importance of the prerace inspection and follow-up examinations of identified horses cannot be overstated. Evidence exists that horses with prior pathological conditions are at increased risk for recurrent or more severe injury, possibly career-ending or catastrophic.^{3,4}

A veterinarian is present in the paddock, where horses are saddled, and at the starting gate. An injury or lameness requires prompt evaluation and contact with the stewards

for a late withdrawal. The track veterinarian is the ultimate authority over all horses in the paddock and on the race-track during racing and training.

Racing officials rely on the veterinarian for information and guidance. Objective data on injuries may assist the track superintendent to address concerns about the track surface and dispel rumor and exaggeration among horsemen. The stewards and judges need the veterinarian's input regarding the use, safety, and validity of new equipment such as shoes, bandages, protective eye covering, bridles, and therapy modalities. The official veterinarian also can be an invaluable source of information on medication for private practitioners, horsemen, and racing officials.

A brief comment on managing spills is appropriate. A *spill* is defined as a sudden fall of horse and rider that usually causes other horses and riders to fall. Ideally, one may call for immediate assistance from other veterinarians and experienced track personnel to assess and attend promptly to more than one horse injured in the incident. Horses may rise after a spill, although seriously injured, and move to other areas on the racetrack, thus further complicating the situation. A prompt overall assessment of the number of horses involved, the location on the track, and the major injuries is essential to prevent misallocation of resources. Triage and communication, with preferably one experienced veterinarian coordinating the activities, are key to an efficient professional outcome.

MANAGEMENT CONSIDERATIONS

Efficient management of an on-the-track catastrophe while maintaining the horse's best interests is the primary objective. The key elements required include trained personnel, equipment, and communication.

Communication is critical to make the best use of available resources. The track veterinarian must be prepared to respond to the injured horse and direct support personnel and equipment at the scene. The injured horse is under the care and direction of the track veterinarians until it is moved to a clinic or stable to be attended by a veterinarian employed by the owner or trainer. A stable veterinarian may be called to the scene for severe injuries and if time permits. The track veterinarian acts promptly to attend to the injured horse on the track, thus facilitating an efficient transfer for further evaluation and treatment. Efficiency is important for the care of the injured horse and to allow the official veterinarian to be in position for subsequent races without undue delay. Ideally a communication network of two-way radios and mobile telephones works well to keep an orderly process in motion. Radio communication with track departments such as security is used to relay information as required.

The operator of the horse ambulance should have sufficient training to fully understand the ambulance features and how to use them. Knowing how to back up and position the loading doors properly is essential. Failure to accomplish these basic skills could cause further injury or delay proper treatment.

In most situations, track personnel are the first on the scene of the injured horse, but in some countries, such as those of the United Kingdom and Ireland, a veterinarian follows the race and would be on the scene immediately. Track personnel routinely are equipped with radios and are

crucial for initiating communication with veterinarians and providing the immediate care. Knowing who and how to call for assistance can save valuable time and distress for all involved.

Those individuals should be instructed in the basics of emergency care. The track veterinary department should provide such instruction to ensure a defined, reliable standard, without confusion and delay. Topics such as restraint, controlling hemorrhage, support of an injured limb, and when to apply a splint are well worth the time. Most if not all persons are willing to do whatever may be required to assist an injured horse, but they are often reluctant for fear of making a mistake. These first-line providers of emergency care should be encouraged and recognized for their valuable assistance. Splint selection and application should be kept as simple as possible to avoid potential legal complications, which fortunately are uncommon. An overzealous and poorly trained person may assume too much responsibility, however, placing the horse at risk of further injury and subjecting track management to extensive liability. Outriders, who monitor training in the mornings, may be instructed in using a commercially available support, such as a Kimzey splint (Kimzey, Woodland, California, United States). The splint may be applied safely whenever loss of support in the fetlock joint is obvious, because the splint is simple, quick to apply, and generally well tolerated. Restraint is often a critical issue for horse and handlers' safety. Usually keeping the horse quiet and still while supporting a distal limb injury is adequate until a veterinarian arrives to provide professional care. However, in some situations the horse is best kept recumbent (e.g., a horse with such a severe injury that it is unable to remain standing, even with assistance). Such horses may lunge repeatedly and fall, risking further injury and endangering all present. A fallen rider near the horse may be incapable of movement for several minutes while being attended, making control and restraint of the horse all the more imperative.

EQUIPMENT

Substantial improvements in equine ambulance design have contributed to minimizing secondary injury and complications, increasing the chances of saving seriously injured horses. The ambulance should be partitioned, be well ventilated, allow ample daylight, and be equipped with interior lights. Sturdy, rubber floor matting and padded sidewalls, all easily washed, are required. A partition separating the horse holding area and a forward compartment provides a storage area and some protection for handlers. Ideally the ambulance trailer can be lowered hydraulically to facilitate loading of a severely injured horse and eliminating the need for a rear ramp. Side access doors with ramps provide convenient and safe off-loading, without having to back the horse up or turn it around. An extremely valuable feature is a movable middle partition, which serves as a squeeze chute to help support the horse during transport. A seriously injured horse will make excellent use of this feature by leaning on it or the wall when turning, thus drastically reducing lateral movement and unnecessary weight bearing. The Kimzey Equine Ambulance is an excellent example of such a fully equipped vehicle.

The ambulance should be well equipped with splints and bandaging materials. Splints to support the metacarpophalangeal (fetlock) joint are essential, as are compression boots in two or three sizes. Bandage material should include sterile pads, gauze and cotton bandages, and elastic and adhesive wraps. Sufficient material to make a modified Robert Jones bandage always should be available. Duct tape is an excellent means to secure a heavy support bandage or splint, preventing shifting and providing axial stability. Inflatable compression splints are sometimes helpful to stabilize carpal fractures, but application of a cotton-and-elastic bandage is often faster and more effective.

Some of this material can be kept in the equine ambulance, but space and security considerations require that most of the splints and medications are kept in a track vehicle that transports the veterinarians. Emergency supply bags can be equipped and organized to facilitate quick access at the location of the injured horse.

Containers of ice should be kept on board the ambulance during racing for prompt application to horses with acute injuries. Rubbing alcohol is also useful for cooling horses in warm climates.

Although it is not frequently required, a portable oxygen supply with a simple flow delivery system and two endotracheal tubes should be readily available. A sling of suitable design to support a horse for extended periods is recommended (Liftex, Warminster, Pennsylvania, United States).

MEDICATION

Security concerns may preclude keeping medications in the ambulance in some jurisdictions. An emergency bag with selected drugs is an efficient means to attend to an injured horse on the track and in the ambulance. A suggested inventory includes butorphanol, xylazine, flunixin meglumine, ketamine hydrochloride, detomidine, hydrocortisone sodium succinate, epinephrine, phenylbutazone, and euthanasia products. It should be noted that the American Association of Equine Practitioners Euthanasia Guidelines (2007) state that the sole use of skeletal muscle relaxants is unprofessional and inhumane; however, the guidelines do not preclude the use of these drugs as an adjunct to a barbiturate or other acceptable drugs to facilitate a humane procedure. These can be a valuable aid to safely manage an uncontrollable horse that cannot be removed from the racetrack for euthanasia. An assortment of syringes, needles, tourniquet, scalpels, scissors, hemostats, and blood collection tubes complete the emergency kit.

TRAINING INJURIES

Humeral Fractures

During morning workouts and gallops, horses are subject to the same injuries as those that occur in racing. A few injuries, such as humeral fractures, are not encountered commonly in racing, but they are often seen while horses are only galloping. For the reporting period of 1993 to 2000, 12 of the 15 humeral fractures observed occurred during morning training.⁵ Horses with spiral humeral fractures, with or without displacement, almost always are considered candidates for immediate euthanasia. The injuries usually involve the horse falling suddenly and

remaining down, although some do rise. The rider may have no warning before the fall, but some horses may change leads and bobble or shorten the stride.

The diagnosis is straightforward if the horse is standing. The horse bears little or no weight, and the limb is in a hanging position, with the horse unable to advance the leg if encouraged to move. There may be obvious swelling of the area, and palpation or manipulation with auscultation often reveals crepitus. Horses that are down on the track when the veterinarian arrives are diagnostic challenges. They may make some attempt to rise, particularly with encouragement, but with the fractured humerus on the down side they are rarely successful. Rolling the horse over can be accomplished with at least two people and the use of shanks or similar equipment to avoid being kicked in the process. Once the horse is turned over, the fracture is often apparent and the horse may rise with the good forelimb down. These horses often fall dramatically when the fracture occurs and may be slow to recover because of the shock of both the fall and the fracture.

Although some injured horses may be loaded and transported to the stable, no treatment is recommended other than analgesia and physical support. These horses are extremely difficult to load without the assistance of capable and readily available personnel. Loading becomes substantially more difficult with time, and the increased swelling and pain make the horse reluctant to move at all after several minutes. A horse is best left supported on the equine ambulance until the stable veterinarian arrives to confirm the diagnosis before euthanasia. At the request of an owner, or to satisfy insurance requirements, radiography may be attempted to document the diagnosis, particularly for horses with minimally displaced fractures. For most horses with this severe injury, radiographs are obtained more humanely post mortem. Humeral and scapular fractures do occasionally occur during racing, and horses should be managed in the same manner.

Collision Injuries

Collision injuries usually are associated with training, because many horses are often on the track, exercising at various speeds, distances, and directions. Maintenance equipment and personnel moving on and near the training surface, open gaps permitting access to the track, and insufficient outriders to monitor and control the congestion all predispose to collision injuries with other horses and inanimate objects. Injuries may be of any type but include trauma to the head, axial skeleton, shoulder, and pelvis. Bruising and lacerations from impact are not uncommon. The severity can range from minor abrasions and contusion to severe, life-threatening fracture and hemorrhage.

Location of Injuries on the Racetrack

Considerable anecdotal and published information exists regarding the location of injury occurrences on the track surface.^{5,6} Any injury type can be encountered at any point in a race, and trained personnel should be prepared to respond to any location. From experience, it is safe to conclude that most catastrophic injuries occur in turns and in the stretch run to the finish. Most racing operations position the equine ambulance in the area of the ½- to the ¼-mile pole to be available for a prompt response.

Many injuries are evident immediately after a race and when horses are pulling up and begin galloping back to be unsaddled. Horses with carpal chip or proximal sesamoid bone (PSB) fractures and new or recurrent tendonitis or suspensory desmitis usually show lameness after they are pulled up. The jockeys should alert an outrider for assistance. Some riders may be hesitant to pull up and dismount because of inexperience and uncertainty, but the track veterinarian should make this policy clear to the jockeys and encourage conservative, prudent decisions. Any horse suspected of being lame, by a jockey or outrider, should be held at that location until evaluated by an official veterinarian.

Horsemen, riders, and officials often express concern about unsafe track conditions. Extreme conditions, such as freezing, washouts, and gross discrepancies in uniformity, may be potentially hazardous. However, muddy or sloppy conditions are not a significant risk factor for serious injury, but they may contribute to rundown injuries, the bruising and abrading of soft tissue at the palmar or plantar aspect of the fetlock from contact with the track surface. Random injuries can cause poor performance. Most catastrophic injuries occur on a fast racetrack.^{3,5-7} Muddy and sloppy tracks usually produce numerous late withdrawals and smaller fields, especially if a race was originally scheduled for the turf. Thus some degree of selection of horses occurs in these races. In addition, horses that are not in contention and showing response entering the stretch on a poor track usually are not encouraged persistently by the riders. They are allowed to ease themselves, a situation that may not occur on a fast track with the rider more optimistic of a good finish.

PUBLIC RELATIONS AND MEDIA ISSUES

The track veterinarian must be keenly aware of humane considerations and prepared to respond to questions from the media, patrons, horsemen, and track personnel.

In situations that expose the public to catastrophic injuries in the racehorse, the track veterinarian also must be cognizant of esthetic considerations, such as using screens and covers to eliminate unnecessary viewing of horses and the process of euthanasia. During racing, time constraints may become critical to management. Most seriously injured horses can be supported, loaded, and transported for further evaluation off the track. On-track euthanasia should be reserved for those few horses for which no other alternatives exist.

During the 1990 Breeders Cup at Belmont Park, catastrophic injuries resulted in the euthanasia of three horses and considerable media attention. The need for more efficient liaison with the media was demonstrated clearly. In response, the American Association of Equine Practitioners initiated the "On Call" program at the 1991 Kentucky Derby and has continued this program to date. The program consists of veterinarians with media training who donate their time to respond to questions from the media regarding equine health care concerns. The "On Call" veterinarian is available to provide accurate and expert commentary, answering vital questions during a busy event, thus releasing the event veterinarians to attend the injured horse. More than 100 equestrian events are supported by an "On Call" veterinarian each year.

RACING INJURIES

Fractures of the Forelimb

Fractures range in severity from relatively minor chip and nondisplaced incomplete fractures to open, comminuted fractures of long bones, which are considered the most severe on-the-track catastrophes. Fortunately the latter are rare. Available data support the clinical findings that most fatal fractures involve the forelimb and that most of these fractures are of the carpus or more distal part of the limb.¹ This section provides an overview of the most common types of fractures that are encountered on the racetrack, beginning with the foot and working proximally in the forelimb and hindlimb.

Foot and Pastern

Fractures of the distal phalanx are often articular, but they may be nonarticular and involve only a palmar process. An affected horse usually completes the race or begins easing in the later stages, rather than pulling up abruptly. Distal phalanx fractures commonly are diagnosed after the race while the horse is on the track or is cooling out. Lameness may vary in intensity, but it usually increases to non-weight-bearing status within 30 to 60 minutes. Moderate-to-severe lameness is present, without palpable swelling. Nondisplaced third metacarpal bone (McIII) or proximal phalangeal fractures should be considered as a differential diagnosis. If the lameness is apparent at a walk, a compression boot to stabilize the limb distal to the carpus may be useful until other fractures are ruled out. Distal phalangeal fractures are not as commonly diagnosed on the track as fractures of the proximal phalanx, and some may be missed initially, only to be diagnosed later and go unreported.

Middle phalangeal fractures are rare as a primary injury and usually are seen as part of a multiple injury breakdown of the fetlock and pastern.

Fractures of the proximal phalanx usually occur suddenly during a race or while the horse is pulling up. Such fractures range from an incomplete fracture to varying degrees of fragmentation and severe comminution. Most horses with these fractures are lame and require prompt analgesia and application of a supportive splint or bandage. These horses do not tolerate a heavy compression boot well. Displaced fractures are diagnosed readily on the track. These require considerable attention to provide adequate support for transport to prevent further bone and soft tissue damage, thus optimizing the chances of repair and recovery. Proximal phalangeal fractures are the most commonly diagnosed injury of the pastern and occur equally in the left and right forelimbs.

Metacarpophalangeal Joint

The metacarpophalangeal joint is involved in most catastrophic injuries. Horses with simple, nondisplaced condylar fractures of the McIII usually develop acute lameness at the end of a race or after the race. Lameness is noticeable at a walk by the time the horse is loaded. With minimal swelling, diagnosis is presumptive initially, and appropriate supportive measures are required. Although the lameness may be substantial, localizing the injury is often difficult when displacement and swelling are minimal. However, some condylar fractures of the McIII are diagnosed after the horse has returned to the stable to cool out,

without the assistance of an ambulance. An open, comminuted McIII condylar fracture causes severe lameness. The horse is pulled up during a race or immediately after the race. The proximal aspect of the displaced fragment penetrates the skin with some mild hemorrhage, making the diagnosis readily apparent.

Because the potential for further displacement and contamination is great, considerable care must be exercised to support the fracture site. Preferably a sterile bandage should be applied to the area and then the limb supported with a heavy bandage or compression boot. Excessive movement of the horse should be avoided while the horse is loaded and transported on the ambulance. Newer ambulances are equipped with a sliding partition to support the horse firmly. The prognosis is guarded because of the compound (open) nature of this injury, and extreme care in managing these horses on the track is essential to a successful outcome.

Proximal Sesamoid Bones

The PSBs are a frequent site of racing and training injury. The PSBs of the forelimbs are primarily involved. Classically, a simple fracture of a PSB results in a progressive lameness while the horse is cooling out after successfully completing a race or workout. The official veterinarian may not see many of these horses and may learn of their injuries only after receiving information from the test barn personnel, trainers, or attending veterinarians.

A more severe sagittal or midbody fracture of one or both of the PSBs causes severe, acute lameness during a race or immediately after a race. If only one PSB is involved, the loss of support of the metacarpophalangeal joint is minimal. The limb should be held by the first attendant on the scene, to prevent weight bearing and further movement, before application of a Kimzey splint. Once supported, these horses are relatively cooperative and confident to move for loading and transport.

In horses with biaxial PSB fractures, loss of metacarpophalangeal joint support is immediate. A dramatic drop of the metacarpophalangeal joint occurs whenever the horse attempts to bear weight. The limb must be supported immediately and the horse controlled to allow prompt application of a splint. These horses may attempt to move on the injured limb and, if they are not restrained, may cause substantial secondary damage to the soft tissues of the fetlock joint (see Chapters 36 and 104).

Fractures involving the metacarpophalangeal joint frequently are complex and involve some combination of condylar fractures of the McIII and PSB fractures, thus compromising the suspensory apparatus. Horses running at race speeds that sustain a McIII condylar or PSB fracture continue to gallop several strides on the injured limb before pulling up. Often they may unseat the rider and gallop considerable distances before being stopped. Additional fractures and disruption of the suspensory ligament (SL) and distal sesamoidean ligaments may result, and the injury may become open, with subluxation and disarticulation of the metacarpophalangeal joint. Depending on the severity of the injury, some of these horses may be manageable for ambulance transport. However, many require immediate euthanasia because of the extensive damage. The metacarpophalangeal joint is involved in two thirds of all catastrophic racing injuries at the New York Racing Association tracks.⁵

Third Metacarpal Bone

Condylar fractures of the McIII were discussed previously. Horses with minimal displacement of the fracture have a good prognosis for return to racing after surgery. Those with substantial displacement of the fracture or skin penetration have a less favorable prognosis, but with proper on-track management, many can have a reasonable outcome in an alternative career.

The McIII diaphysis is the site of a common racing and training injury referred to as *bucked shins* (see Chapter 102). If not properly managed, horses with bucked shins may not stride out well, move with a choppy action, and trail the field during a race. These horses may be pulled up by the jockey, but they require little on-track care.

Dorsal cortical fracture of the McIII may result from the bucked-shin complex and is an injury that is seen most frequently in late 2-year-olds or in 3-year-olds. Lameness may be intermittent, and palpation of the affected area often provides inconsistent findings. Dorsal cortical fracture of the McIII poses a serious risk to horse and rider if not detected and properly treated. If a horse with a fracture is returned to training and racing prematurely or the fracture is undiagnosed, a complete diaphyseal fracture may develop. This catastrophic injury causes a horse to fall without warning during morning workouts or a race, risking serious injury to the rider and others in close proximity. The track veterinarian is faced with an essentially unmanageable horse. The fracture usually is comminuted and open. The limb distal to the fracture site is often attached by only tendons and remaining skin. The horse may attempt to rise or manage to rise, but it is extremely unstable and usually falls again. For the safety of all assisting at the scene and for the riders who may still be down on the track, the horse should physically be kept down by capable track personnel. Immediate euthanasia is indicated. If the trainer or owner is present and requests another opinion, the attending veterinarian can sedate or anesthetize the horse long enough for another veterinarian to be summoned. Attempts to develop an anesthetic protocol to facilitate transport of these horses for potential surgical intervention have been unsuccessful. Historically, this catastrophic injury has been the cause of spectacular horse spills in racing, causing considerable loss to the horse industry, serious jockey injury, and negative media attention. Because essentially no treatment alternatives are available, all effort must be directed toward prevention. Accurate diagnosis and the removal of horses from high-intensity training and racing are essential.

Carpus

Although the carpus is a frequent site for lameness, it is seldom an area associated with catastrophic injury (see Chapter 38). Carpal chip and slab fractures cause a range of clinical signs. Small chip fractures may be difficult to detect and, without obvious effusion or pain on palpation, are difficult to differentiate from McIII condylar fractures. A horse with a carpal slab fracture, especially if displaced, is usually severely lame. If a slab fracture is suspected, the carpus should be supported with a cotton wrap and elastic bandage or an inflatable compression splint. Comminuted carpal fractures occur and cause collapse of the proximal and distal rows of carpal bones and obvious instability. Although a horse with numerous carpal fractures may fall,

most horses pull up abruptly, stopping in just a few strides. The horse is in acute distress and non-weight bearing and usually is difficult to load and transport. If possible, a horse with a comminuted carpal fracture should be examined by consulting veterinarians, because euthanasia may be highly likely. Such examination avoids unnecessary movement and distress for the horse. Some horses may be salvaged for breeding purposes with surgery and extensive nursing care.

Radius

Radial fractures are rare. For an 8-year period, four horses were destroyed because of comminuted radial fractures. It is interesting to note that all four horses sustained a fracture of the left radius.⁵

Shoulder

Fractures of the shoulder, though rare, are always catastrophic. Those of the humerus most often occur during training and were discussed previously (see page 962). The scapula may fracture during a race, and in my experience the injury always involves the joint. The horse may fall suddenly, but some horses manage to pull up in the race without going down. Horses are severely lame and have rapid, severe swelling from hemorrhage, great difficulty in advancing the limb, and a dropped shoulder appearance. This is an excellent example of the benefit of viewing the entire horse from a short distance before commencing a close-up examination.

Inexperience with this injury often leads the clinician to an early misdiagnosis of a lower limb problem, only to be frustrated and embarrassed when enlightened by lay assistants. Swelling over the area may become extensive in a few moments but may be overlooked if one remains focused on assessing the distal aspect of the limb. On numerous occasions, support splints have been applied to the limb distal to the carpus, with the shoulder recognized as the primary injury only when attempting to load the horse onto the ambulance.

Nevertheless, once the diagnosis is made, the horse may be difficult to load, even with abundant help. As a rule, horses are more willing to attempt to move shortly after the injury occurs. Once loaded, the use of a movable partition for support is a tremendous aid. Euthanasia is best performed while the horse is still in the ambulance.

Fractures of the Hindlimb

Pastern

Fractures of the hind phalanges occur considerably less frequently than in the forelimb. Similar injuries occur, but fractures of the proximal phalanx predominate. Only 10 proximal phalangeal fractures of a hindlimb were diagnosed for the period 1993-2000 at the New York Racing Association tracks, compared with 28 for the forelimbs.⁵ Horses appear considerably more able to support on only one hindlimb, and to protect the injured site from further weight bearing, than to support on only one forelimb. Open fractures are much less common than in forelimbs, and the prognosis for horses with hindlimb fractures is better than for those with forelimb fractures. A lightweight splint and bulky bandage are recommended, because horses do not tolerate a heavy splint or boot well. Complex

fractures involving the proximal and middle phalanges and the third metatarsal bone (MtIII) may be seen, although these are rare.

Third Metatarsal Bone

MtIII condylar fractures occur less commonly than those seen in the McIII. Horses do not tolerate the weight of a compression boot on a hindlimb and often do better with a thick support bandage. It is important to obtain good-quality radiographs, because many of these fractures are located medially and have a tendency to spiral, making surgical repair a challenge.

Tarsus and Tibia

Fractures of the tarsus are an uncommon cause of acute training and racing injuries. Osteoarthritis of the distal tarsal joints commonly results in reluctance to break from the gate and overall poor performance, but it rarely causes an acute on-track incident.

Catastrophic tibial fractures are rare and generally result from preexisting stress fractures (see Chapter 45). Complete fracture may occur hours after a race or training, when the horse is moving about and resting in the stall. In horses with obscure hindlimb lameness, scintigraphic examination is a valuable diagnostic aid for preventing catastrophic injury.

Stifle and Femur

Femoral fractures are rare in the racing Thoroughbred. Osteochondrosis lesions of the distal aspect of the femur are not uncommon and cause subtle hindlimb lameness that is often difficult to diagnose (see Chapter 46). Stifle lameness, including that caused by osteochondrosis lesions, often leads to compensatory lameness conditions. Tarsal or stifle problems may not cause catastrophic injury primarily but rather lead to a compensatory forelimb lameness and secondary breakdown, often involving the PSBs and metacarpophalangeal joint. Accurate diagnosis and treatment of many mild-to-moderate lameness conditions often helps prevent more serious injury.

Acute hindlimb lameness, other than that caused by complete tibial or femoral fracture, is generally difficult to assess on the track. The horse may pull up abruptly or be lame at the completion of a race and often is reluctant to bear weight. Unlike those with forelimb lameness, horses with acute severe hindlimb lameness are often relatively easy to load into an ambulance and transport with minimal effort. The clinician must keep in mind that a horse may have an incomplete fracture, such as of the MtIII. Thus maximizing support while the horse is in the ambulance and walking the horse minimally should be standard care for these horses.

Pelvis

Pelvic fractures can cause acute hindlimb lameness and occur predominantly in fillies while racing or training (see Chapter 49). From 1993 to 2000 at the three New York Racing Association tracks, a diagnosis of pelvic fracture was made in 20 horses, 17 of which were fillies.⁵ A horse with a pelvic fracture is in obvious distress and reluctant to move, but with proper analgesia and physical assistance, most horses can be loaded and relocated carefully to a stall. Extreme care must be taken, because displacement of the

fracture is a potential risk, specifically in horses with ilial wing or shaft fractures. Severe hemorrhage and death can occur even when a horse is in an ambulance or stall. This potential for fracture displacement and hemorrhagic shock keeps survival numbers discouragingly low. Of the 20 horses with pelvic fractures, six horses died within 1 hour, and 11 were euthanized at the scene or less than 1 week after injury.⁵ With increased use of scintigraphy and early diagnosis of stress-related bone injury, the hope is that catastrophic injuries such as displaced pelvic fractures can be avoided.

Head and Axial Skeleton

Horses involved in collisions or spills may sustain any number of head or spinal injuries. Loose horses attempting to jump railings and run through gaps frequently fall, but they seldom sustain serious injury. Young horses not uncommonly become fractious while being saddled, rearing, lunging, and occasionally falling. Horses with obvious injury, regardless of the severity, should be withdrawn from the race immediately. The track veterinarian must take responsibility for withdrawing a horse after a fall, often consulting with the trainer or owner. The most serious head injuries usually result from flipping in the saddling paddock and striking the hard ground or a wall partition. Sinus hemorrhage, although dramatic and at times copious, is generally not a serious concern. Horses that sustain a hard blow to the head may become disoriented and show ataxia initially. Prompt treatment with corticosteroids and dimethyl sulfoxide may be indicated while the horse is kept quiet in a reasonably safe area. Horses should be led to and held in a grass paddock away from trees and fences. If ataxia subsides, the horse may be moved to a stall by ambulance or by walking with attendants.

I find it interesting that some horses may appear normal immediately after a hard fall and head trauma, only to become dull and ataxic or reluctant to move after a short time. Initial conservative management is recommended for any horse after a hard fall. The horse should be monitored closely while moving to the stable, and track personnel should communicate their concerns personally to the attending veterinarian whenever possible. A horse that sustains a serious fall resulting in fractures at the base of the skull is often recumbent, has aural hemorrhage, and unfortunately dies quickly. Fractures or other injuries of the axial skeleton may occasionally result from falling, but a definitive diagnosis may be difficult to make. A horse may be stunned or winded, may remain recumbent after falling, and may make no attempt to rise. Vital signs are usually normal. After it is ensured that the airway is unobstructed and after the saddle has been removed, the horse is given time to rise. Oxygen from a continuous-flow mask and an intravenous corticosteroid (hydrocortisone sodium succinate, 100 to 500 mg) are recommended. It may be 30 minutes or longer before a winded horse is ready to get up. When ready, and with a mild prompt of a slap on the neck or rump, many horses then stand unassisted. Some may be slower and assume a sternal position briefly before rising. Those that are unstable and appear weak behind will need assistance, by helping lift on the tail.

If a horse attempts to rise unsuccessfully several times even with assistance, rolling it on its other side may be best. Injury to the down limb may have occurred. A horse

with fractures of the cervical or thoracic vertebrae makes little or no attempt to move, depending on the level of injury.

Horses that are down on the track with normal vital signs and no apparent limb injury must be presumed to have injury of the axial skeleton. The horse can be positioned on a mat while still recumbent and carefully pulled onto the ambulance for transport to the stable or emergency clinic. An anatomical diagnosis may be established, but the prognosis is poor for horses that have not stood successfully by 12 to 24 hours.

Soft Tissue Injuries

Injuries sustained at the speeds of racing and training workouts are often complex, with soft tissue and bone injury. Fracture of a PSB or the McIII causes abrupt loss of action and compensation by the horse and concomitant reaction by the rider. Several strides may follow with some weight bearing on the affected limb. What began as a simple fracture may progress to a catastrophic, life-threatening injury in only seconds because of progressive soft tissue and bony disruption.

The soft tissues supporting the metacarpophalangeal joint are particularly prone to injury. Disruption of the digital flexor tendons or SL can cause gross hyperextension of the metacarpophalangeal joint and potential damage to the digital vessels and nerves. Inadequate perfusion of the injury site may limit or prevent a successful surgical repair or other attempts at recovery.

The metacarpophalangeal joint may subluxate with a primary soft tissue injury. This usually results from a traumatic disruption of the suspensory apparatus, although complete disruption of the digital flexor tendons also may be involved secondarily. If the luxation is closed, the joint may become locked in hyperextension, requiring manual reduction before a splint can be applied. If open luxation occurs, the distal aspect of the McIII can be seen. Complete luxation usually results from a complete disruption of the SL or the distal sesamoidean ligaments. Immediate support of the limb and splint application are essential for a closed injury. A horse with an exposed, open fetlock injury must be euthanized on the track.

Digital Flexor Tendon Injuries

Digital flexor tendon injury (tendonitis) primarily involving the superficial digital flexor tendon (SDFT) is a substantial cause of economic loss in the Thoroughbred industry. Tendonitis varies in severity, but horses with even the most minor tear require time to recover and return to training. Racing data from the three New York Racing Association tracks support a recurrence rate approaching 25% for horses with tendonitis.³ The overall rate is clearly higher when one considers horses lost to follow-up or reinjured before reaching racing fitness.

Acute tendonitis is usually not apparent on the race-track and usually is diagnosed by the attending veterinarian several hours later. Severe or total disruption of a SDFT causes obvious lameness at the completion of training or a race. Lameness usually increases rapidly, and hyperextension (dropping) of the metacarpophalangeal joint is apparent.

Recurrent tendonitis is usually more severe than the initial injury. A horse may pull up before completing

training or a race. Swelling is often substantial, the mid-metacarpal region lacks definition, and the metacarpophalangeal joint drops moderately. The degree of swelling may preclude accurate diagnosis of what soft tissue structure is involved. The prerace inspection is particularly important in horses with a history of tendonitis, because this may be the determining factor in preventing reinjury. Careful palpation for sensitivity and swelling can reveal subtle changes that may have gone undetected by the trainer and exercise rider, because these horses usually continue to train without obvious lameness. The track veterinarian may require an ultrasonographic evaluation before permitting the horse to race. Comparison with previous examination findings may demonstrate a clinically significant lesion, although the horse is sound at the trot and gallop. Despite all efforts, tendon reinjury occurs to some horses during racing or in workouts. When reinjury does occur, the application of a compression boot or splint is required. Horses with severe tendonitis, even with loss of metacarpophalangeal joint support, can heal with time to become pasture sound.

Digital flexor tendonitis in a hindlimb is unusual, but tendons are vulnerable to severe laceration and blunt trauma by being cut down during a race. Injury may occur when the foot of a following horse strikes the tendons of the hindlimb. The shoe, particularly one with a toe grab, may lacerate and completely sever the SDFT and less commonly the deep digital flexor tendon. Wounds often are badly contaminated, and prognosis is guarded because of complications from infection. A clean support bandage is applied initially, and light sedation and analgesia are given. Further splinting is usually unnecessary and is not well tolerated. Immediate transport to an emergency hospital is strongly advised.

Suspensory Ligament Injuries

Injuries of the SL and digital flexor tendons have many similarities, are relatively common, vary considerably in severity, and predominantly involve a forelimb. Branch or body desmitis often is detected after the morning exercise when the horse is cooling out. Moderate or severe desmitis causes acute lameness, possibly with some degree of metacarpophalangeal joint drop, but swelling may initially be minimal. A presumptive diagnosis is made while the horse is still on the track, but differentiating between a SL and digital flexor tendon injury may be difficult. An important principle in emergency management is providing immediate support. A splint that supports the metacarpophalangeal joint is always indicated whenever suspensory disruption is suspected. Obvious dropping of the metacarpophalangeal joint during weight bearing reinforces the decision to use a standard Kimzey splint. PSB fractures often may occur concomitantly, but they may not always be readily apparent. Progressive loss of metacarpophalangeal joint support occurs as the severity of suspensory tearing increases. If the injury is closed, the on-track management remains the same. Complete SL disruption and disarticulation of the metacarpophalangeal joint was discussed previously (see page 966).

The distal sesamoidean ligaments are a vital component of the suspensory apparatus, and even mild desmitis should be considered a serious injury in Thoroughbred racehorses. Horses with mild desmitis look similar to those with digital flexor tendon or SL injuries. These injuries may

appear to heal, but recurrence is common and problematic. My strong clinical impression is that horses with previous distal sesamoidean desmitis are at risk to develop catastrophic injury, and close monitoring of the status of these injuries is imperative when horses return to training. Any indication of recurrence of desmitis is sufficient cause for retirement or at least additional time off for reevaluation. Reinjury is often catastrophic, with complete rupture of the ligaments, proximal displacement of the PSBs, and disarticulation of the metacarpophalangeal joint with multiple secondary injuries. Euthanasia usually is required for these horses.

REGULATORY CONSIDERATIONS

Attending veterinarians must be aware of their responsibility to the regulatory body, that is, the state racing commission or its equivalent. Some jurisdictions require a written report to be filed for any horse euthanized on official racetrack grounds. In lieu of a formal report, a good policy is to contact the track stewards and state or association veterinarian to inform them of catastrophic injuries that occur during training or racing. A necropsy and samples for pathological examination may be commission requirements and are vital for statistical evaluation of injuries at the racetrack. Important information can be obtained relative to the nature of the injury, track condition, age and sex of the horse, and other possible risk factors. The official track veterinarian, whether state or association, is fully knowledgeable of commission requirements and appropriate procedures and so is a valuable source of information for the veterinary practitioner on the backstretch. Free exchange among professionals is mutually beneficial. The official veterinarian frequently requires the prompt assistance of the stable veterinarian to continue the management and treatment of a seriously injured horse.

EUTHANASIA AND INSURANCE

When attending to a horse with a catastrophic injury, the veterinarian should instruct the owner to notify the insurance carrier, if applicable, as soon as possible. In the event that euthanasia is not immediately essential but is later considered, most insurance companies require a second opinion. Horses with catastrophic injuries may require immediate euthanasia at the scene on the racetrack when supporting and loading the horse onto the ambulance is not possible. Regardless of the circumstances, thorough documentation with photographs of the injury and specifics of the incident should be maintained. If possible, radiographs should be obtained to document the nature of the injury. It is always advisable to have a representative of the stable present to provide consent for euthanasia, but this is rarely the owner. When consent cannot be obtained, the veterinarian on the scene must do whatever is indicated to alleviate distress and protect the horse from further injury until a consulting veterinarian arrives.

On rare occasions the veterinarian may be confronted with an uncontrollable horse or a situation in which euthanasia is the only course of action remaining, consent and consulting opinion being unavailable. After exhausting reasonable attempts to stabilize the horse and obtain assistance, the professional decision for euthanasia can be

exercised without excessive concern. Documentation in these horses should include necropsy examination. Although the situation is extremely unlikely to result in a legal challenge, thorough communication and documentation are always advisable. Euthanasia is the final option available to the clinician and is justified to prevent further pain and distress. Although the technical aspects of the procedure are simple, resulting in a fast and humane death for the horse, veterinarians must exercise discretion and sensitivity. As disturbing as the situation may be for the attending veterinarian, there is no way to gauge the

emotional and esthetic impact on others who might be present. Persons with direct connections to the injured horse, track workers, media representatives, and patrons may all be within viewing range. An effort to screen the horse from onlookers during euthanasia and while removing the body is recommended. Those immediately connected with the horse should be afforded the opportunity to leave, although some will wish to remain. Finally, the veterinarian must remain in control of the scene, being cognizant of not only the needs of the horse, but also the concerns and safety of all others present.

Chapter 104

Catastrophic Injuries

Dean W. Richardson

Surprisingly, it is difficult to define exactly what comprises a catastrophic injury, but one definition might be any injury that will unquestionably end athletic function and will require extensive treatment to save the horse's life. Comminuted fractures, severe limb lacerations with major vascular damage and extensive tissue loss, and ligamentous injuries leading to overt joint instability are straightforward examples and are easily categorized as "catastrophic." Problems arise when the gross appearance of an injury is initially not representative of its severity or when the severity of the injury is overestimated because of its gross appearance. The attending veterinarian often has to calm the client long enough to allow proper decision making. Most horses with catastrophic injuries can be stabilized well enough to be transported to a referral facility, or at least long enough to permit a complete investigation of therapeutic options and probable outcomes. A quick decision to euthanize might be the easiest and best option, but in some instances it may not be correct, and it most certainly is not revocable.

General principles for emergency first aid of severe distal limb injuries are as follows:

1. Immobilize with a dorsal splint that aligns the phalanges with the third metacarpal bone (McIII). This can be either with a prefabricated splint (e.g., Kimzey Leg Saver, Kimzey, Woodland, California, United States; Figure 104-1), or with a stave of split polyvinylchloride (PVC) pipe or something similar over a lightly padded bandage. The dorsal splint should extend from the proximal aspect of the McIII to the ground, covering the entire dorsal aspect of the hoof wall. The heel must be pulled upward toward the dorsal aspect of the splint to align the phalanges with the McIII. If a prefabricated splint is not available, a lightly padded bandage with a splint applied to the dorsal aspect of the metacarpal region, phalanges, and hoof serves the same purpose if the heel is kept elevated. This can be done by taping the heel and a

heel wedge with nonelastic tape (e.g., duct tape) to the dorsally applied splint. Excessive padding should be avoided because it allows dorsal flexion within the bandage and shifting of the splint. A prefabricated splint is not ideal for all injuries because it may not provide medial-to-lateral stability, but it is usually adequate for first-aid stabilization. For injuries involving the upper limb a Robert Jones Bandage

Fig. 104-1 • A Kimzey Leg Saver has been applied to the right forelimb of a racehorse with traumatic disruption of the suspensory apparatus. Note that the distal aspect of the limb is held in position with a dorsal splint attached to a footplate that keeps the phalanges in alignment with the third metacarpal bone. When splinted horses usually comfortably bear weight when walking, they stand with the splinted limb forward in a flexed non-weight-bearing position (as shown). Excessive load is placed on the contralateral limb. Limb length disparity occurs as a result of the added length of the splint, making it necessary to elevate and pad the contralateral foot (not shown).

with splinting material incorporated within the bandage should be applied (see Chapter 86).

2. Tranquilize or sedate adequately to minimize further injury and allow examination. Xylazine or detomidine is usually adequate.
3. It is often difficult to know the exact nature of an injury without using diagnostic imaging, so *do not* make assumptions. If possible, immobilize the area of injury and transport the horse to a referral center for evaluation.
4. Do not hesitate to use parenteral antiinflammatory agents and analgesics. Many attending clinicians worry that antiinflammatory therapy may prompt an injured horse to use a limb, causing further damage; unless perineural analgesia is used, a horse with an injured limb will be unlikely to sustain further injury under the influence of parenteral medication.
5. If there is any skin damage, the horse should immediately be given broad-spectrum antimicrobial drugs intravenously.
6. Transport an injured horse in a *tight* stall, as tight as it can be, so that the horse can easily lean against side walls for support. Do not tie the head tightly. In general, horses with forelimb injuries should be transported facing backward, and those with hindlimb injuries facing forward.
7. Most important, do not make rash decisions concerning treatment and prognosis.

The reader is referred to Chapter 86, and there are two excellent recent reviews that detail emergency stabilization of equine fractures.^{1,2}

TYPES OF CATASTROPHIC INJURIES

Traumatic Disruption of the Suspensory Apparatus

Traumatic disruption of the suspensory apparatus is almost exclusively an injury that occurs in the forelimbs of Thoroughbred (TB) racehorses, but it can occur in the hindlimbs and in Standardbred (STB) and Arabian racehorses. It may occur more often in North America than in Europe, although any horse running at high speed may sustain this injury, including young foals that are chasing the dams in a pasture. Speed alone does not account for the injury, and it is likely that fatigue of the flexor muscles supporting the fetlock joint and digit leads to higher stresses in each component of the suspensory apparatus. There also may be a history of the horse being bumped or making a misstep.

The history and clinical presentation of adult horses with traumatic disruption of the suspensory apparatus are straightforward, because the horses are either breezing or racing and pull up acutely and severely lame. The fetlock joint drops as the horse attempts to bear weight. Many horses become anxious or even frantic as they attempt to control the injured limb. Obvious swelling and pain are present over the site of the injury. In foals the diagnosis is often not made as quickly.^{2,3} The typical history of a foal with traumatic disruption of the suspensory apparatus (or lesser injuries of the suspensory apparatus) is of being turned out in a large field with its dam and other mares and foals shortly after birth, or after confinement to a box stall for an extended period. As the mare runs with the other horses, the foal attempts to keep up, running at speed and to the point of exhaustion. This results in the same

Fig. 104-2 • Lateromedial (left) and dorsopalmar radiographic images of a Thoroughbred racehorse with traumatic disruption of the suspensory apparatus as a result of comminuted fractures of both proximal sesamoid bones. The radiographs were obtained with the horse in a non-weight-bearing position. This horse later underwent successful surgical management using fetlock arthrodesis.

combination of speed and fatigue that leads to this injury in racehorses. The clinical signs of complete disruption of the suspensory apparatus in foals are similar to those in adult horses but less dramatic.

The hallmark clinical signs, fetlock drop and severe lameness, are seen in horses with complete disruption of any portion of the suspensory apparatus. The most common injury in both adult horses and foals is fracture of both proximal sesamoid bones (PSBs) (Figure 104-2). The fractures are often comminuted, especially in the basilar portions. The second most common type of traumatic disruption of the suspensory apparatus is complete avulsion of the distal sesamoidean ligaments. This is easily recognized radiologically by the proximal displacement of the intact PSBs (Figure 104-3). The least frequently recognized type of traumatic disruption of the suspensory apparatus is a complete tear of the body or both branches of the suspensory ligament (SL) (Figure 104-4). The Paso Fino, Peruvian Paso, and some other older horses have a degenerative condition of the SL that leads to suspensory apparatus failure that is particularly problematic in the hindlimbs. However, these horses do not have acute, severe lameness, which is typically seen in racehorses (see Chapter 72). In horses with traumatic disruption of the suspensory apparatus, excessive extension of the fetlock may result in stretching and damage to the digital vessels, which may cause avascularity or hypovascularity of the digit. Simultaneous damage to the superficial and deep digital flexor tendons is also common and should be assessed ultrasonographically if there is a suspicion of severe injury. Although PSB fractures and suspensory injuries are both common hindlimb injuries, the most severe breakdown injuries usually involve the forelimbs.

Fig. 104-3 • Lateromedial (*left*) and dorsopalmar radiographic images of a Thoroughbred racehorse with traumatic disruption of the suspensory apparatus as a result of complete rupture of the distal sesamoidean ligaments. Proximal displacement of the proximal sesamoid bones and hyperextension (drop) of the fetlock joint can be seen in these weight-bearing radiographic images.

Fig. 104-4 • Lateromedial radiographic image of a horse with traumatic disruption of the suspensory apparatus as a result of a nearly complete tear of the body of the suspensory ligament. A similar appearance is observed in horses with severe injury of both branches of the suspensory ligament. Dorsal subluxation (hyperflexion) of the proximal interphalangeal joint occurs as a result of suspensory ligament disruption. Surgical or nonsurgical management can be chosen in horses with this injury.

Traumatic disruption of the suspensory apparatus is virtually always a career-ending injury. The only exceptions are horses with simple, displaced midbody fractures of both PSBs that can be individually repaired and suspensory body or branch injuries in some STBs. It is important

to recognize the severity of the injury so that an informed decision can be made concerning treatment. Most horses can be saved as pasture sound or breeding horses, but treatment often is prolonged and expensive regardless of the therapeutic approach selected.

First Aid

As outlined previously, an important principle is to align the McIII and the phalanges using a homemade splint or a commercially available splint (see [Figure 104-1](#)). I much prefer the commercially available splint. Most horses are less anxious and are able to move comfortably immediately after the splint is applied. Other first aid measures include the administration of nonsteroidal antiinflammatory drugs (NSAIDs), intravenous fluids to replace water and electrolytes lost through sweating, and broad-spectrum antibiotics. Antibiotics should be given even if the fracture is ostensibly closed. High concentrations of antibiotics in the fracture hematoma are desirable, because skin abrasions and lacerations over hypovascular tissue are common. The vascularity of the foot should be assessed by palpation of the digital vessels and assessment of hoof temperature. Aspirin may be of some value in limiting the vascular injury. Horses that are extremely anxious and difficult to calm should be given xylazine or detomidine, with or without butorphanol, as needed for restraint and to prevent further self-injury.

Nonsurgical Management

Nonsurgical management involves long-term splinting with a goal of achieving sufficient fibrosis of the injured tissues that satisfactory support of the fetlock returns. The primary advantage of this approach is avoiding the risks associated with operating in a hypovascular and possibly contaminated surgical site. The surgical and technical

expertise and equipment required are modest, and the expense of *initial* treatment is relatively small. There are serious disadvantages of nonsurgical management. Developing fibrosis may not be adequate to support the fetlock joint in a horse exercising at pasture; this is more problematic in horses with distal sesamoidean ligament avulsions than fractured PSBs. Scar tissue may slowly fail when stallions enter a breeding shed or a mare carries a foal. Most horses are uncomfortable on the splinted limb and cannot use it normally because of an abnormal posture (see [Figure 104-1](#)), and they are at risk for supporting limb breakdown and laminitis. Long-term splinting also demands meticulous daily bandage changes to prevent rub sores at the proximal dorsal metacarpal region and suppurative dermatitis of the palmar aspect of the pastern and heel bulbs. In my opinion, nonsurgical management is not the best choice in most horses with traumatic disruption of the suspensory apparatus, especially those with comminuted fractures of the PSBs, or rupture of the distal sesamoidean ligaments.

Successful long-term splinting of horses with traumatic disruption of the suspensory apparatus involves meticulous nursing care. Most clinicians use a prefabricated splint because of the ease of its removal and application. The Kimzey splint can be improved for long-term use by welding on a heel extension to increase the load-bearing surface area. This helps minimize the tendency to develop rub sores at the proximal, dorsal edge of the splint. The prefabricated splints are not perfectly fitted for every horse. Therefore some modifications in padding may be required to avoid excessive pressure at the proximal, dorsal metacarpal region. Regardless of which type of splint is used, the limb should be checked daily for developing sores or dermatitis, particularly in the palmar aspect of the pastern. If the leg is washed, it should be dried before a bandage is applied. Skin infection can be very difficult to manage. Both systemic and local antibiotics are usually necessary. A shoe with a thick pad and heel elevation should be applied to the contralateral foot. A thick shoe is necessary to mitigate the limb-length discrepancy that exists when the contralateral limb is splinted, but it is difficult to give an exact degree of heel elevation.

The most critical decisions when using nonsurgical management of a horse with traumatic disruption of the suspensory apparatus with splints are when to remove the splints and how to gradually return the horse to more normal fetlock and digit joint angles. Upright splinting is used in most horses for approximately 6 weeks, but many, particularly those with distal sesamoidean ligament avulsions, may require much longer. The process of dropping the fetlock should be gradual. This can be done by splinting at decreasing angles (a difficult task when using a prefabricated splint) or using a fetlock support shoe incorporating an adjustable sling. Horses should be confined to a stall for a prolonged period (4 to 6 months), because a single misstep can lead to tearing of the still-maturing scar tissue. Although external coaptation has worked well in individual horses and in some clinicians' hands, long-term results do not appear to be as good as surgical arthrodesis (fusion). Surgical fusion has considerable potential complications, but solid fusion of the fetlock joint is unlikely to slowly fail and cause progressive discomfort in horses used for breeding. Horses in which nonsurgical management was used appear to have more long-term lameness problems when compared

with those in which surgical management was used. The more serious the injury, the less likely it is that a nonsurgical approach will prove satisfactory. Although a splint will definitely allow adequate early management, both laminitis at 6 to 8 weeks postinjury and chronic pain or instability when the splint is removed occur commonly.

Surgical Management

Surgical management of horses with traumatic disruption of the suspensory apparatus generally involves fetlock arthrodesis, although repair of simple, displaced midbody fractures of the PSBs can be performed to preserve some degree of fetlock joint function. The major advantage of arthrodesis is that the procedure usually affords the horse immediate, comfortable use of the limb and, barring surgical infection or failure, avoids the problems associated with prolonged overload of the contralateral limb. Because the fixation is usually very stable, postoperative immobilization is minimal, and the various complications of casts and splints can be avoided. The primary disadvantage of surgical arthrodesis is an increased risk of infection when compared with nonsurgical management. In addition, successful arthrodesis requires both surgical expertise and investment in equipment and facilities.

The most widely used technique for fetlock arthrodesis is the application of a dorsal plate and the creation of a tension band on the palmar aspect of the fetlock joint.³ Dorsal plating without a tension band on the palmar aspect of the fetlock is ill-advised because the plate is cycled in bending and the fixation may fail. Cyclic fatigue of even a large bone plate consistently results in plate failure unless a tension band technique of some sort is used. There are small variations in the techniques preferred by experienced surgeons with this procedure, but all have the same primary mechanical goals. I currently use a 10-hole, broad locking compression plate with a combination of 5.0-mm locking head screws and 5.5-mm cortex screws, and two 1.25-mm wires placed in figure-eight fashion along the palmar aspect of the fetlock joint.

The major complication of internal fixation for fetlock arthrodesis is infection. However, because this repair is very strong and stable, healing can occur even in the face of infection. The combination of instability and infection, however, rarely results in success, and reoperation on horses with unstable, infected sites is usually necessary to achieve fusion. Implant failure also is a concern, but proper technique and the use of large screws make this complication uncommon.

A common long-term complication associated with traumatic disruption of the suspensory apparatus is osteoarthritis of the proximal or distal interphalangeal joints. The joints are stressed by the fusion of the fetlock joint and often by the presence of serious injury to the digital flexor tendons and distal sesamoidean ligaments that insert on the phalanges.

Many horses with traumatic disruption of the suspensory apparatus sustain open, contaminated fractures or such extensive soft tissue damage that internal fixation may carry an unacceptable risk of infection. External skeletal fixation is an alternative means of managing horses with such injuries (see Chapter 87).

The prognosis for any horse with traumatic disruption of the suspensory apparatus depends on the specific nature

and severity of the injury. Horses with distal sesamoidean ligament avulsions have a poorer prognosis than those with displaced fractures of the PSBs, because the latter tend to form fibrous scar tissue more quickly. Horses with the relatively uncommon suspensory body or bilateral branch tears have the best prognosis, because they seem to heal more quickly and have less fetlock joint instability. At least 60% to 75% of horses with closed disruptions of the suspensory apparatus and an intact blood supply should be saved with proper treatment. Horses with open injuries have a much poorer prognosis regardless of the therapy chosen, and those with open injuries with vascular compromise have a very poor prognosis.

Additional complications of traumatic disruption of the suspensory apparatus, regardless of treatment, include laminitis or breakdown of the contralateral limb. The primary complications of long-term splinting are rub sores and inadequate fibrosis, which lead to instability and chronic pain.

Other Catastrophic Distal Limb Fractures

Horses with other distal limb fractures have highly variable prognoses, but most horses with catastrophic fractures of the distal extremity can be successfully treated (for life if not function) if proper first aid and technically competent surgical treatment are performed. It is critical to prevent skin penetration of bone fragments, vascular injury, and prolonged delays in treatment. Because distal limb injuries can nearly always be temporarily immobilized relatively easily, decisions to euthanize should be made only after having informed discussions with the owner.

Severely comminuted fractures of the proximal and middle phalanges can be managed with the relatively simple technique of transfixation pin casting (Figure 104-5).^{4,5} The important advantages of transfixation techniques are that they are technically easy to perform and provide consistent early comfort. Without an open approach to the fracture site the surgeon can avoid causing further damage to already severely compromised tissues. The major disadvantages of transfixation techniques are

Fig. 104-5 • Lateromedial and dorsopalmar radiographic images of a horse with a comminuted fracture of the proximal phalanx stabilized using transfixation pin casting. This type of fixation allows immediate weight bearing and obviates the need to invade the fracture site and further compromise injured soft tissues. Eventually both the metacarpophalangeal and the proximal interphalangeal joints will fuse, but horses with catastrophic phalangeal fractures can be salvaged using this technique.

catastrophic fractures through the pin holes and early loss of acceptable comfort from pin loosening or infection.

Horses with major fractures above the carpus and tarsus are not as easy to deal with humanely on an emergency basis. It is certain that any overtly unstable fracture in the proximal limb will be an extremely expensive proposition to address surgically and that the prognosis is always guarded to poor at best. The only common exception might be horses with humeral fractures that may successfully heal with just stall confinement.

Chapter 105

Track Surfaces and Lameness: Epidemiological Aspects of Racehorse Injury

Tim D.H. Parkin

The racing surface is often regarded as the most important factor likely to influence the risk of injury. The effect that different course designs and surface types have on injury

has been discussed for many years,^{1,2} and the surface and its management are obvious targets for immediate scrutiny after a racing injury. Certainly there are significant differences in the risk of injury among races held on turf, all-weather, and dirt tracks. On turf tracks there is also a significant effect of the firmness of the ground on injury risk. However, there are many other potentially less obvious factors that may also be related to the type and quality of the racing surface that influence the risk of injury during racing. In this chapter, the strength of evidence provided by a range of epidemiological studies is examined. Associations between injury and surface characteristics during both racing and training are described. The risk of injury on different surfaces and evidence from multivariable epidemiological studies that include surface characteristics are summarized. Comparisons of the same racecourse where changes have been made are discussed, and priorities for future research are identified.

RACING SURFACES

The Risk of Injury on Different Racing Surfaces

Musculoskeletal injuries are the most common reason for time lost in training, retirement from racing, and euthanasia in racehorses worldwide.³⁻⁷ In the majority of locations, nonturf surfaces appear to be associated with an approximately twofold greater risk of injury. From 1999 to 2003 in the United Kingdom, the overall incidence of catastrophic distal limb fractures (including fractures of the carpus and tarsus) in all-weather flat races was 0.74 per 1000 starts compared with 0.37 per 1000 starts in turf flat races.⁸ The risk of catastrophic musculoskeletal injury on dirt has been reported to be 1.12 per 1000 starts compared with 0.58 per 1000 starts on turf on two racecourses in Ontario, Canada.⁹ The risk of fracture injury for horses racing on three New York Racing Association tracks from February 1, 1983 to mid October 1985 was 2.1 per 1000 starts on dirt compared with 1.1 per 1000 starts on turf.¹⁰

Results in a study from Florida did not concur.¹¹ In this study the incidence of injury was significantly higher in turf races (2.3 per 1000 starts) than in dirt races (0.9 per 1000 starts).¹¹ This may be a particular characteristic of racing in Florida because the turf races were more likely to involve larger fields and be longer races than those reported in other studies. Both of these factors were associated with the risk of injury in previous studies,¹²⁻¹⁷ indicating that turf racing may be a proxy marker for these other risk factors.

Fractures predominate as a major type of injury, and the bones distal to the carpus or tarsus are most often affected.^{3,4} Postmortem investigations conducted in the United Kingdom have enabled estimates of the risk of different types of fracture on different racing surfaces (Figure 105-1).⁸ The overall incidence of catastrophic distal limb fractures in all-weather flat races was 0.74 per 1000 starts compared with 0.37 per 1000 starts in turf flat races. In other words, the relative risk (RR) of catastrophic distal

limb fracture on all-weather surfaces compared with turf was 2.0 (95% confidence interval [95% CI] 1.3 to 3.1). There were also significant differences in the risk of certain types of fracture on these surfaces. In particular, fractures of the lateral condyle of the third metacarpal bone (McIII) were 3.2 times (95% CI 1.6 to 6.6) more likely to occur on all-weather surfaces than turf racecourses, and biaxial proximal sesamoid bone (PSB) fractures were 4.6 times (95% CI 1.8 to 11.6) more likely to occur on all-weather surfaces than turf racecourses.⁸ Some fracture types were more common on the turf. For example, catastrophic fractures of the proximal phalanx were twice as common (RR 2.0; 95% CI 0.6 to 6.7) on turf than on all-weather surfaces.⁸

Similar postmortem studies have been conducted in other racing jurisdictions. In California^{3,18} and Kentucky^{14,19} the PSBs followed by the McIII were the most common sites of fracture. These were catastrophic fractures included in the California Horse Racing Board postmortem program from dirt tracks^{3,18} and all injuries recorded at four tracks in Kentucky.^{14,19} In contrast, injuries on three New York Racing Association dirt and turf tracks from 1986 to 1988 were more similar to those in the United Kingdom, with fractures of the McIII being most common.²⁰ Information on fatal musculoskeletal injuries from a number of racing jurisdictions within the United States (33 racetracks in 15 different states) revealed that McIII fractures were slightly more common than those of the PSBs.²¹ However, an unknown number of “ankle breakdowns” in these data would have been caused by a PSB fracture and suspensory apparatus disruption. PSB fractures were also reported as the most common “serious accident” on eight racecourses in Japan.²² In Australia, the situation is more similar to that in the United Kingdom, with fractures of the McIII and then of the PSBs predominating.²³ Clarification of differences in the risk of individual fracture types on different surfaces and further international comparisons will aid in the understanding of the pathogenesis of different fractures and ultimately may result in novel preventative measures being developed.

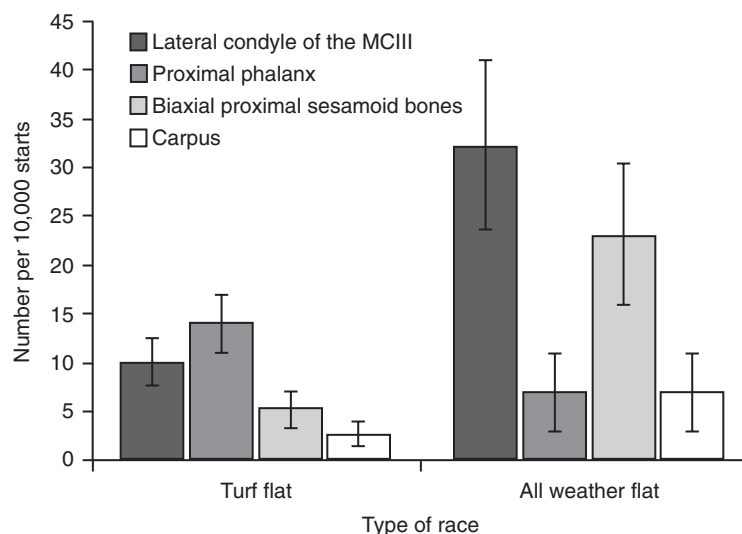

Fig. 105-1 • The distribution of catastrophic forelimb distal limb fractures on UK racecourses, by flat race surface type, from January 1999 to December 2003 (showing standard error bars). *MCIII*, Third metacarpal bone.

Simple comparisons of injury rates are useful in establishing priorities for future work at the local or regional levels. However, when establishing causal relationships, raw comparisons should be interpreted with caution. To state that the differences in injury rates on different surfaces in different racehorse populations are directly caused by surface characteristics is dangerous. There are many differences in the Thoroughbred populations racing in different locations. For example, at the time of the following study, different shoe types such as toe grabs were permitted in the United States.²⁴ There were strong associations between the use of toe grabs and the risk of both suspensory apparatus failure and condylar fracture of the McIII. In particular, the risk of suspensory apparatus failure was substantially increased in horses using regular-height toe grabs compared with those using no toe grabs.²⁴ In many other racing jurisdictions, toe grabs are not permitted, so meaningful international comparisons need to account for differences in shoe types as well as many other important contributory factors.

Even within a racing jurisdiction, direct comparisons between turf and all-weather tracks should not be made without consideration of all potential explanatory factors. For example, in the United Kingdom the prize money available and class of flat race held on the all-weather racecourses are generally lower than for flat races held on turf. This is obviously potentially an important confounding factor, as one of the reasons for poor performance may be subclinical or previous injury. It is therefore possible that horses in all-weather flat races are inherently more likely to sustain an injury, regardless of the surface on which they are racing. The type of surface may be important, but it is imperative to consider all potential factors in the same

analysis. In order to deal with confounding variables, epidemiologists build multivariable or multiple regression models. These models adjust the size of effect and significance of risk factors by accounting for the effect of other confounding variables that are associated with both the outcome and other explanatory variables (Figure 105-2).

Further examples of potential confounding variables include track configuration,²⁵ training regimens of the local trainers who most often use the tracks,²⁶⁻²⁸ and weather conditions and experience of the jockeys.²⁹ All of these variables and many more should be considered and accounted for when interpreting differences in injury risk on different racing surfaces. A causal web can be built to account for all potential confounders. A simplified version of the causal web designed for investigations of fatality during racing in Victoria, Australia^{30,31} is shown in Figure 105-3. It is particularly useful with such complex diagrams to divide variables into the different horse, race, track, and jockey factors and then to identify which of these factors

Fig. 105-2 • An example of the relationship among explanatory, confounding, and outcome variables that should be accounted for when determining the true size and significance of associations between important risk factors and the outcome of interest.

Fig. 105-3 • Causal web for consideration of risk factors and interactions among them for fatality during racing in Victoria, Australia.^{30,31}

are likely to influence others as well as affecting the likelihood of the outcome of interest.

Evidence from Multivariable Epidemiological Studies

There are relatively few multivariable epidemiological studies that have included surface type in models while also accounting for the effect of many other factors. The likely reason for this is that when performing case-control studies it is common to select control (unaffected) horses from the same race in which the case horse was running. This obviously means that race-matched case-control sets are also matched on surface type, making comparison of this factor impossible. The rationale behind this study design is that in order to identify horse-level factors it is easiest to exclude (by matching) the potentially strong influence that race-level factors may have on the outcome. Even among studies that have specifically investigated race-level factors, control races, in which no horses were injured, are often matched on race and surface type.¹⁷ This is done to account for the strong effect of race type and surface on injury risk so that other, more subtle race-level risk factors can be identified. Given the fact that until recently the majority of courses were not in a position to change their track type, the priority was to identify modifiable risk factors to reduce the likelihood of injury on the surfaces already in use.

Results from the few multivariable studies that did include surface type have not been consistent. In New York, racetrack location (one particular track) and dirt surfaces were significantly associated with an increased risk of injury.^{20,32} However, in Florida, horses racing on turf tracks were more likely to be injured than those racing on dirt.¹¹ This association remained significant even when field size and race distance (both associated with surface type) were accounted for.

Therefore, to date complex multivariable models have not fully addressed the effect of surface type on injury risk. Ideally, large-scale collaborations among racing jurisdictions with different racing surfaces, using multivariable analysis to account for other potential risk factors, are needed if firm conclusions are to be drawn. Although expensive and time-consuming, such an initiative would also help to avoid repetition of studies and duplication of investment in different jurisdictions investigating the same problems. Large-scale collaborations can dramatically improve statistical power, ensuring that small effects of different risk factors can be identified.

Studies within the Same Racecourse

The goal of most multivariable epidemiological studies is to identify modifiable risk factors to enable the design and implementation of appropriate and effective interventions. In the field of racetrack epidemiology, monitoring the effect of a change is as close as the industry will get to a randomized controlled trial. If all other factors remain the same and sufficient time is given for interventions to have a statistically significant effect, a change in one variable (e.g., surface type) may be interpreted as causing a change in the outcome variable (e.g., risk of injury). Although there has been a change from dirt to synthetic surfaces at a number of tracks around the world, to date few have reported how these new surfaces have affected injury rates.

It is likely too early to see statistically significant differences in changes of surfaces on racetracks in the United States. However, in Japan, changes were made to Hanshin Race-track after it was found to have a higher rate of racing injuries than other racetracks.²⁵ Changes included slowing the pace of races, widening the third and fourth corners, and including an upgrade slope in the finishing stretch. A better cushion was installed in both the turf and dirt tracks. In the following year there were significant reductions in the incidence of severe racing injuries (both fracture and nonfracture).²⁵

In 2000 the British Horseracing Authority established an Equine Welfare database that provides all race, horse, course, trainer, jockey, and racecourse details for every race on all 60 racecourses in the United Kingdom. Comparison of the risk of fatality and long-term injury on the different courses before and after the introduction of new surfaces provides some of the most convincing evidence available to assess the effect of surface type on injury risk. These data were provided by members of the Equine Science and Welfare department at the British Horseracing Authority.³³ The synthetic surfaces at three all-weather racecourses were replaced or relayed from 2001 to 2007. At two of these tracks the surface was changed to Polytrack from either Equitrack or Fibresand. At a third track an old Fibresand surface was replaced by a new Fibresand surface that was subsequently relayed 2 years later.

The change from Fibresand to Polytrack on one course resulted in a statistically significant reduction (50%) in the risk of fatality (RR 0.48 [95% CI 0.3 to 0.78]; $P = 0.002$). However, there was no significant reduction in the risk of long-term injury on this track ($P = .026$). In contrast, a change from Equitrack to Polytrack on a second course resulted in a significant drop in the risk of long-term injury (RR 0.37 [95% CI 0.2 to 0.7]; $P = 0.002$) but no significant change in the risk of fatality ($P = 0.73$).

These studies demonstrate that all aspects of course design must be considered to enable the provision of the safest racing conditions. On some courses with certain climatic conditions, turf may be the only appropriate surface. However, in other situations, synthetic surfaces (especially the more recent designs) may present a similar level of risk as turf. All racing jurisdictions should endeavor to provide the best racing conditions and seek the most robust current evidence when deciding which surface to introduce. In addition, comparisons and subsequent judgments on success or failure should be made only once sufficient time has passed for statistically significant differences in risk to be identified.

Quality of the Racing Surface

Turf Tracks

The firmness of the turf racing surface was reported as a risk factor for musculoskeletal injury.^{6,17,34} In all studies there was an approximately linear increase in risk of injury from heavy and soft going (footing) through to firm or hard. The firmer the surface, the greater the risk of injury. Racing on firm or hard ground increased the risk of catastrophic lateral condylar fracture of the McIII fivefold, compared with racing on anything between good-firm and heavy.²⁹ Harder tracks, with less moisture content, may have less cushion, causing greater forces to be exerted and

increasing the risk of injury.³⁵⁻³⁷ This may be the case for most fracture types, but when lateral condylar fractures of the McIII were investigated, there was a threshold of good-firm going, above which the risk was greatly increased. Observations such as these could help elucidate the true pathogenesis underlying what is believed to be a stress-related fracture.³⁸ Further studies to identify methods to both effectively measure and modify the track firmness, specifically in jump racing, in which lateral condylar fractures of the McIII are most common, are warranted.

All-Weather Tracks

Recently there has been considerable interest in the replacement of dirt surfaces with new synthetic surfaces, particularly in the United States. Anecdotally the effect on injury rates has been variable. There remains much to learn about track maintenance with newer surfaces, and a particular type of synthetic surface may be more suitable than others in certain locations with particular climatic conditions. It may be years before statistical analysis of injury rates can be performed; therefore it is essential that accurate records of the number of starts and injuries be maintained for all tracks to enable effective future comparison.

Synthetic surfaces may lose the properties that make them safer than dirt surfaces, and inappropriate maintenance may well result in significant deterioration of the surface. Based on race data from the United Kingdom from 1987 to 1993, the overall fatality rate in all-weather flat races was determined to be 0.6 per 1000 starts compared with 0.8 per 1000 starts in turf flat races.⁴ At the time there were only two all-weather racecourses in use, both of which were still relatively new, having started racing toward the end of 1989. In contrast, today starts at all-weather tracks in the United Kingdom are significantly more likely to result in injury or fatality than starts at turf tracks.^{6,8} All-weather surfaces must be installed to customize maintenance regimens and surface characteristics with prevailing local weather conditions.

TRAINING SURFACES

It is understandable that the focus of epidemiological studies be race day fatalities and injuries, because they attract much media attention and have a substantial impact on the public perception of racing. In addition, epidemiological race day data are much more readily available than training data, simplifying study design and logistics. Training injuries are extremely important, and given the amount of time at risk there are many more nonfatal injuries during training than racing. One study in the United Kingdom followed a population of approximately 1200 horses for 2 years and reported that 78% of nontraumatic fractures occurred during training.³⁹ It is important to consider the effect of the training surface on lameness incurred during training and also during racing. The quality, type, and maintenance of training surfaces are at least as important as the same aspects of the racing surface. However, to date there are relatively few studies that have investigated the effect of different training surfaces on injury or lameness.

In some racing jurisdictions where the majority of training occurs at the same location as racing and sometimes on the main racetrack itself, it is difficult to compare the effects

of different surfaces. However, in other jurisdictions, such as the United Kingdom, the vast majority of training occurs on private or public gallops located away from racecourses, and in this scenario there are many other factors that may contribute to differences in injury rates on different surfaces (e.g., training regimen, topography, and population demographics). Therefore identifying definitive associations with surface type has proved difficult. Nevertheless, there are differences. There is a higher incidence of dorsal metacarpal disease on dirt than on wood fiber training surfaces in the United States.⁴⁰ Horses in the United Kingdom that spent a majority of time training on Equit-rack were less likely to develop a fracture than those training on other surfaces.⁴¹ During a study investigating racecourse catastrophic fracture a marginal association with the use of sand gallops during training was identified.²⁶

Recent work from Ontario, Canada indicated that catastrophic musculoskeletal injuries were more likely to occur on turf (0.64 per 1000 workouts) than on dirt (0.39 per 1000 workouts).⁹ Although not statistically significant, these differences are in contrast to the findings of previous studies and defy the common perception that turf is the safer surface. There is limited detailed discussion in the report, and results may be an example of an unavoidable limitation of observational epidemiological studies. Such studies identify associations, but often it is impossible to determine cause or effect. Horses may have been trained on turf, a more forgiving surface, because they were not as sound as those training on dirt. Turf-trained horses may have been inherently more likely to sustain a catastrophic musculoskeletal injury, regardless of the surface on which they were being trained. A further example of this potential effect was seen in a study in the United Kingdom,^{26,29} in which horses doing no fast work during training were found to be significantly more likely to sustain a catastrophic distal limb fracture during racing. Bones of these horses may not have been adapted and may have been at risk to fail when racing, or the horses may have had sub-clinical injury or preexisting pathology that prevented them from training at full speed but increased the likelihood that they would sustain a fracture during racing.

Horses training in the United Kingdom on an unnamed all-weather surface were eight times more likely to have sustained a pelvic or tibial stress fracture.²⁸ Horses were included if they had been trained on this surface 70% of the time during the exposure period (30 or 60 days before fracture date). Horses that had trained less than 70% of the time on one surface were defined as the reference group (mixed surfaces), with which other surfaces were compared. The 70% cutoff was arbitrary. Incline and maintenance of the training surface were not taken into consideration, and there was a significant degree of unexplained trainer-level variability.²⁸ Further investigations measuring other trainer- or training yard-level variables are required before definitive statements about the effect of training surfaces on injury and lameness can be made.

FUTURE DIRECTIONS

Physical properties of racing surfaces and injury rates were studied. As early as the 1970s a dynamic testing machine was developed to simulate the peak impact force of a horse's hoof on a racing surface.³⁵ There was a decreased

risk of lameness on surfaces with a loose cushion and soft base in a survey of racecourses in California conducted at the same time as the testing machine was being used.³⁵ Significant differences in surface moisture content at six different locations around Canterbury Downs racecourse, Shakopee, Minnesota, were identified, even though the subbase moisture did not change significantly.¹³ Several areas of abnormal compaction were identified at starting chutes and areas of the course exposed to high traffic density.^{13,42} During the study six horses broke down in the compacted areas. More recently, moisture content of the track cushion was shown to alter the energy return and impact resistance.⁴³ It is interesting to note that these authors also suggest that these properties may be optimal for horses traveling at relatively narrow ranges of speeds. Given the potential differences in the way individual horses interact with the racing surface⁴³ and the fact that tracks are not uniform,^{13,42} there is a requirement for large-scale population level studies using accelerometers (in conjunction with Global Positioning Systems [GPSs] and heart rate monitors) to monitor hoof-surface interactions during normal training.

Accelerometers placed on different anatomical locations are now being used more frequently. In the early 1980s, accelerometers placed on the dorsal aspect of the hoof showed typical decelerations on a sand track of 85 g

(g = acceleration of gravity, 9.8 meters/sec²) on impact.³⁶ This author also cited Fujisawa (personal communication), who reported that the typical deceleration on impact on turf was 175 g compared with 84 g to 125 g on dirt. Promising recent developments in wireless data acquisition systems (WDASs) suggest that population-wide studies are not far off. A WDAS was used to identify significant differences in impact accelerations in horses using toe grabs compared with flat racing plates⁴⁴ and on different surfaces.⁴⁵

The potential to use the horse as the device to measure hoof-surface interactions is being pursued by a number of groups around the world. Technological advances have reduced the cost and weight of GPSs and accelerometers. Assuming jockey and horse safety are not compromised, WDASs will enable population studies to be conducted during normal training. The volume of data acquired will require specialist analytical techniques so that these data can be combined with routinely collected training, medical, and racing data to enable new risk factors for injury and lameness to be identified. These risk factors will be at the level of hoof-surface interaction and will provide novel insights into the pathogenesis of many different injuries. Only then will the true extent of the role the surface plays in the development of injury in the Thoroughbred be realized.

Chapter 106

The North American Thoroughbred

*Rick M. Arthur, Jeff A. Blea, Mike W. Ross,
Patrick J. Moloney, and Mark W. Cheney*

DESCRIPTION OF THE SPORT

King James I of England established horse racing as the Sport of Kings in the early seventeenth century, and the earliest English immigrants brought the sport to the American colonies. Colonials imported fine-blooded horses and staged informal race meets almost as soon as they hit land. Richard Nicolls took command of New Amsterdam, renamed New York, became the first governor of the colony in 1664, and established a racecourse.

Many of the founding fathers of the new country, including George Washington and Thomas Jefferson, raced horses. John Wickham, Aaron Burr's attorney at his treason trial, lost one of the top American stallions of the emerging Thoroughbred (TB) breed, named Boston, in a card game in 1835. Nathaniel Rives won the difficult 2-year-old colt and ignored advice to geld him. Boston not only won 40 of 45 starts, but he also sired Lexington. A foal of 1850, Lexington became the top racehorse in the country by winning from New York to New Orleans.

Lexington was named for the Kentucky town that became the center of TB breeding. Horsemen quickly realized that healthy horses could be raised on the limestone base of Central Kentucky, and the horse Lexington helped establish the area by becoming the top sire in the United States for 16 years.

Racetracks sprang up in many cities, and although the industry suffered during the Civil War, Saratoga was the exception. The New York social elite took in the waters at the Spa to escape the heat and humidity of the city, attended the races during the day, and partied through the summer evenings in spite of the war. A few years after the conflict, Col. M. Lewis Clark founded the Louisville Jockey Club to conduct race meets in Kentucky. In 1875 the Louisville Jockey Club opened a new racetrack, later called Churchill Downs, and that year Aristides won the first edition of the Kentucky Derby (the Derby).

The Derby did not begin as America's most famous race. Col. Matt Winn's genius at marketing in the early twentieth century was required to create the legend the Derby has become. When the filly Regret won the race in 1915, the Derby rose to prominence quickly as a premier American sporting event and a major stop for 3-year-old TBs.

Fans were disappointed when owner Sam Riddle and trainer Louis Feustel deemed the Derby too early in the year for their strapping colt Man o' War, the horse that had broken many records the previous year, winning 9 of 10 races. However, Man o' War added to his reputation without the Derby, going through a perfect season of 11 wins in as many races. To many he remains the finest TB racehorse the United States has ever produced.

A new moral climate was sweeping the nation after the turn of the century. Gambling, including on horse racing, was banned in many states as a precursor to Prohibition, which began in 1919. Kentucky was the exception, and horsemen and racing fans found many ingenious ways to skirt the law. The need for more state revenue from the Great Depression in the 1930s prompted the ban on racehorse wagering to be lifted in many states. Until the 1970s horse racing was often the only legalized form of gambling in most states. From the 1930s to the 1960s horse racing, boxing, and baseball were the most popular sports in the United States.

War Admiral, sired by Man o' War, gained such a following in the 1930s that the whole country listened to the Seabiscuit-War Admiral match race. Because the older Seabiscuit had lost his first 17 races as a 2-year-old, everyone expected War Admiral to win. Yet Seabiscuit, "the people's horse," beat War Admiral that day, and in 1938 Seabiscuit was said to have had more newspaper space than Hitler.

As a 3-year-old, War Admiral won the Derby, the Preakness, and the Belmont Stakes, races that became known as the Triple Crown. Only 11 horses have ever won all three races. In 1948 Citation so impressively captured the series that some thought the horse replaced Man o' War as the greatest racehorse. That argument persisted for the next 25 years, despite the achievements of horses such as Native Dancer, Swaps, Kelso, and Dr. Fager, none of which won the Triple Crown. However, in 1973 a bright chestnut colt, Secretariat, so captured the public imagination when he won the Triple Crown that *Time*, *Newsweek*, and *Sports Illustrated* all put him on the cover. He won the 1½-mile Belmont Stakes by a spectacular 31 lengths.

Although the Triple Crown increased in stature, California developed a strong racing circuit. Santa Anita, east of Los Angeles, opened in 1934 and gained immediate attention by offering the then unheard-of sum of \$100,000 (U.S.) for the inaugural Santa Anita Handicap. Across town, Hollywood Park began attracting movie stars and established its own fixture, the Hollywood Gold Cup. Bing Crosby and friends built Del Mar about 100 miles south.

As transportation by air became more popular in the last half of the 20th century, horses from the East and West began meeting regularly. In fact, Affirmed, the latest horse to win the Triple Crown, in 1978, prepared for racing at Santa Anita and Hollywood Park.

Regional rivalries became popular, which added to the success of the Breeders' Cup series, inaugurated at Hollywood Park in 1984. Unlike the Triple Crown, which is solely for 3-year-olds, Breeders' Cup Day offers races for various divisions. Two-year-olds show what might emerge at the next year's Kentucky Derby. European horses often invade for the grass events and more recently have achieved notable success on synthetic surfaces. The Breeders' Cup Classic attracts elite runners on the dirt from coast to coast and from abroad.

The Breeders' Cup epitomizes the tenacity of the racing TB. Spectacular victories—including the triumph of Sunday Silence over archrival Easy Goer in the 1989 Classic, the victory of Personal Ensign over the Kentucky Derby-winning filly Winning Colors in the 1988 Distaff, and the devastating move Arazi made to capture the 1991 Juvenile after shipping to the United States from France—are legendary. American TBs regularly compete in Europe, Japan,

Australia, and Dubai. Not even King James I could have envisioned the Sport of Kings developing into the international phenomenon it is today.

TB racing always has been an expensive sport. Since the introduction of pari-mutuel gambling, financial support and revenue have been derived from two groups: racehorse owners and the gambling public. The third leg of the horse racing industry is the racetrack operator. Racetracks are generally for-profit corporations, with the exception of Del Mar, Keeneland, Oak Tree at Santa Anita, and a few others. Racehorse ownership was once the domain of the wealthy, but now opportunities and partnership options are available for many. In the past, most owners maintained breeding operations to supply horses for their personal racing stables; commercial breeders were few. The focus of breeding was for successful racehorses, and rigorous selection for soundness was as important as racing ability. Commercial breeders have now become a major source of racehorses and have a different goal. They produce horses to satisfy the commercial market, an entirely different objective, often unrelated to producing a racehorse.

Commercial breeders offer horses at public auction, primarily as yearlings but also as weanlings and 2-year-olds in training. The auction market is fashionable and in many ways fickle and trendy. Buyers favor precocious yearlings, relatively more mature than others. Yearlings with sprinting bloodlines and well-muscled yearlings sell better than those with a classic distance pedigree and conformation for all but the most expensive horses. Little is known of soundness of the sire and dam. Although these trends are worrisome, one positive consequence has been the ever-improving quality of horse offered at public auctions. Now some of the best-pedigreed horses in the world are sold at public auction, a fact not true 30 years ago, and even traditional owners and breeders have entered the lucrative commercial market.

The commercial market is a straightforward avenue for owners to buy a high-quality racehorse without maintaining broodmares. The September Keeneland yearling sale offers nearly 5000 yearlings over a 10-day period. Numerous other sales are conducted throughout the year. Presale examination is an important part of veterinary practice at racetracks (see Chapter 99). The auction environment can be an extremely high-pressure setting for the veterinarian because the knockdown price may reach millions of dollars.

Owners can also buy horses in claiming races. In claiming races the prospective owner buys the horse for a predetermined price *before* the race, and the horse is considered sold once the starting gate opens, regardless of whether the horse wins or even finishes the race. Purses and monies from purchase (claim) go to the previous owner. Potential buyers of claiming horses cannot examine the horse, but they can watch it walk into the saddling paddock. Buying a horse by claiming gives an owner a ready-made racehorse, whereas owners and breeders have to wait at least 3 years before racing a homebred horse, and yearling buyers have to wait at least a year. Unfortunately, the risks in claiming are considerable, because the claiming game has no honor and the new horse may already be at the end of its career.

Racetrack operators have changed to meet demands of the racing fans. The state, racetrack operator, and horsemen, through purse distributions, obtain income from a

percentage of the moneys wagered, called *handle*. Revenue from simulcasting races across the United States and internationally is now an important source of handle, and Internet and at-home wagering are already realities. There was a time in the 1970s when Santa Anita and Hollywood Park had a higher daily average attendance than the Los Angeles Dodgers baseball stadium. On-the-track attendance has dwindled and contributes only a fraction to purses and commissions compared with what it did 40 years ago, when a fan had to come to the track to place a wager. Unfortunately, for reasons the racing industry is now regretting, the revenue sharing from off-track sites is much less than when the same amount of money is wagered on-track. The amount of revenue generated for purses and racetrack operators has not kept up with inflation, thereby placing greater economic stress on all industry participants. The importance of simulcasting to the future of horse racing has led to consolidation of racetrack ownership.

Because track operators emphasize handle, races are run in a manner to encourage betting. Races must be competitive, and the more horses the better. An anathema to the nongambling race fan and many horsemen is that gamblers bet more money on a large field of poor-quality horses than on a small field of high-quality horses. In the United States, field size rarely exceeds 12 horses, because dirt racetracks are relatively narrow and have tight turns, and turf courses, usually inside of the main dirt track, are even narrower with tighter turns.

Races are made to be competitive by restricting which horses are eligible to run in a particular race. Most important are age, gender, distance, and surface (turf or dirt). Sex and age restrictions limit which horses are allowed to compete in a race. Age is a major factor, and 2-year-olds are never raced against older horses, because they would not be competitive. Distaff races are those restricted to fillies and mares, and although the distaff side is not excluded from open races, such races are seldom competitive, except early in the 2-year-old year.

Distance and surface are conditions selected to suit the horse. Another set of conditions, handicaps and allowances, can be confusing but works well. Handicap and allowance races are set up to even the race by varying the weight carried by the horse. Weight variation is a subjective value, determined by racing officials for handicap races. In allowance races, weight variation is determined by a set of published criteria. For example, 3-year-olds carry less weight than older horses, fillies less than colts, and nonwinners may get additional weight off.

Most races in the United States are claiming races. In claiming races, horses of similar ability are pitted together. Because of the risk of losing a horse by claim, owners and trainers are discouraged from running more valuable horses to steal a purse. The claiming aspect of American racing is popular, but it has several negative effects on racing.

Stakes races are for the best horses. Stakes races require an entry fee and some require an additional starting fee. Stakes races are raced according to sex, age, distance, and surface. Stakes races are graded, listed, or restricted. Restricted stakes races, popular in recent years, restrict eligibility to the state of foaling or to conditions similar to allowance races. Stakes races are run even if only one horse is entered, but this is rare and is called a *walkover*. Stakes can be handicaps, allowances, or weight-for-age races. In

weight-for-age races all horses carry the same weight, except for the well-established allowances for age and gender. The Kentucky Derby is a weight-for-age race for 3-year-olds. All horses are assigned the same weight (126 lb [57.3 kg]), but a filly receives a weight allowance and carries 123 lb (55.9 kg). The best stakes races are graded by a national committee and classified as Grade 1, Grade 2, or Grade 3; Grade 1 races are the top races. The Kentucky Derby and Breeders' Cup Classic are examples of Grade 1 races. The North American graded stakes races are analogous to the European group or pattern races.

Nonstakes races fall into several categories. Maiden races are for horses that have never won a race and can be allowance or claiming races. Races can be restricted to horses that have not won a certain number of lifetime starts. Other specific conditions for races can include eligibility for horses that have not won a race in a certain time period or over a certain distance. Claiming races also are restricted by age, gender, distance, and surface. Although races are devised to maximize competitiveness, the uncertain offering of races for nonstakes horses greatly complicates training and veterinary care, because timing for future races can be difficult to judge.

Stakes races are predominantly for horses 2 and 3 years of age, whereas horses may continue to race in claiming races up to 10 to 12 years of age. Claiming horses may drop progressively in class and value, and the lowest level of TB racing in the United States is considerably below that of the United Kingdom. Much of the following discussion reflects our dealings with high-quality, younger horses. These situations are easier for the veterinarian to be in control and to dictate the diagnostic approach and therapeutic plan, working with the trainer. With low-value claiming horses the trainer is more likely to dictate what is treated and with what. Frequently joints are treated with corticosteroids alone, rather than in combination with hyaluronan. Regardless of level of competition, it is important to establish and maintain a good owner-trainer-veterinarian relationship. This helps ensure the health of the racehorse and the success of the racing venture (JAB).

CONFORMATION

Many mild conformational defects appear to be well tolerated by TB racehorses (MWC, PJM). Mild toe-out and toe-in conformation causes few problems, but horses with moderate or severe toe-out conformation develop interference injuries. Toe-out conformation may predispose the horse to subsolar bruising of the medial heel. The most severe conformational defect is calf-knee or back-at-the-knee conformation. This defect leads directly to carpal lameness. Short, straight pasterns increase concussion, and long, sloping pasterns are undesirable because they may lead to soft tissue injuries or fractures of the proximal sesamoid bones (PSBs). Offset (bench) knee conformation leads to splint disease, injury of the antebrachiocarpal joint, and proximal suspensory desmitis (PSD). Horses that are tied in behind the knee develop tendonitis. Sickie-hocked conformation leads directly to lameness of the distal tarsal region. Horses with straight hindlimbs develop lameness of the stifle region and are prone to upward fixation of the patella.

TRACK SURFACE AND LAMENESS

Track surface is an important factor in the development of lameness and frequently is overlooked or neglected in lameness discussions (PJM, MWC) (see Chapter 105). Track surface dictates frequency and type of lameness. Injuries are often blamed on track surfaces, but musculoskeletal injuries are multifactorial. Shoeing, medication, training patterns, commercial breeding, and many other factors have all been implicated in the high injury rates in racehorses, and as often as not injuries cannot be fairly blamed on track surface (RMA, JAB). The most important factor in fatal racing injuries is not the track surface, but the horse (RMA). Almost all horses that develop fatal musculoskeletal racing and training injuries have evidence of preexisting pathology at the site of the fatal injury. They are repetitive stress injuries. Regardless, track surfaces play an important part in injury development, and the veterinarian needs to appreciate the types of injuries that are likely to develop in the track surfaces in his or her practice area.

Surfaces that favor speed also predispose horses to catastrophic breakdowns. Quality of racing surface is much more important than whether the surface is dirt or turf. Hard racetracks with little cushion are the worst surfaces. One of us (MWC) observed 38 horses with bone injury in a 4-week period when horses were training and racing on a hard racetrack. When sand was added to the track and the cushion increased from 6 to 11 cm, over the ensuing 4-week period only four horses developed bone injury. However, race times increased substantially. Horses need not train on hard surfaces to be able to race on them. Training on a forgiving surface then racing on a fast surface is safer than the opposite approach or working on a hard surface constantly. Consistent and uniform surfaces are the safest, allowing horses to remain sound and reducing incidence of injury (JAB). Track surfaces can change dramatically, especially in inclement weather.

Banking around turns can influence how horses negotiate turns and lameness distribution and expression. The hindlimbs of horses negotiating flat turns appear to slip out from under them, and in some instances horses nearly go down.

Track surface can make a difference in how horses with injuries are managed or rehabilitated. Horses rehabilitating after fractures or other bone injuries should not train on hard tracks. Likewise, horses coming back after soft tissue injuries or racing with minor infirmities should not be trained on deep or muddy tracks.

Many European horses that previously trained on grass now race in North America. Most race and continue to train on grass, but some make the switch to training and racing on dirt successfully (see Chapter 107). Our impression is that European horses appear to have fewer forelimb and more hindlimb lameness problems than North American TBs. European horses often train on long straightaways, and this, combined with a forgiving surface (grass), is a situation different from training on dirt in North America. Horses bred to race on the turf appear to have an inherent conformational difference that allows superior performance on grass. Synthetic racing surfaces fall somewhere between dirt and turf relative to horse surface preferences. Turf horses are much more likely to be competitive on synthetic surface, even if they do not handle dirt tracks.

Just as there are horses that do well or poorly on dirt or turf, there are horses that handle synthetic surfaces well and horses that do not.

In recent years more attention has been placed on track surfaces than ever before. The major change has been the introduction of synthetic surfaces in North America. The first Breeders' Cup events run over a synthetic surface were at Oak Tree at Santa Anita in 2008 and 2009. Synthetic surfaces are primarily sand, some fiber material, and a wax or polymer used to coat the sand and bind the material together. Unlike dirt tracks, which are usually cambered to drain horizontally, synthetic tracks are designed to drain vertically and require a drainage system built into the track. The racing results from synthetic surfaces have been mixed. In California, where the racing commission mandated synthetic surfaces by the beginning of 2008, racing fatalities dropped 40% when main track racing fatalities were compared with the same main tracks when they were dirt from 2004 to 2007. The training fatalities at the same tracks have not significantly improved with the synthetic surfaces. The distribution of racing and training injuries resulting in fatalities has changed. There are many more hindlimb injuries with synthetic surfaces compared with dirt (RMA). There are also numerous reports of increases in soft tissue injuries, primarily involving the proximal aspect of the suspensory ligament (SL). Although synthetic surfaces appear promising, the technology is relatively new, and the synthetic surfaces have had installation and maintenance problems.

A better understanding of the relationship between track surfaces and injury has been woefully neglected in the past. A number of research efforts have begun to better characterize the important relationship between track surfaces, biomechanics, and ultimately injuries. A safe racing surface has become of paramount importance to racing as the highly public injuries to Barbaro in the 2006 Preakness and Eight Belles in the 2008 Kentucky Derby have made equine welfare concerns a public debate. Marketing surveys by the racing industry have shown racing fatalities are of major concern to the general public. There can only be increasing emphasis on equine safety in the future.

MEDICATION AND DRUG TESTING CONSIDERATIONS

Horse racing has always regulated the use of medications, but more recently the relatively permissive North American medication regulatory scheme has come under greater scrutiny. Outside North America most racing jurisdictions operate under International Federation of Horseracing Authorities (IFHA) rules. IFHA rules prohibit the use of nonsteroidal antiinflammatory drugs (NSAIDs) within several days of racing, whereas all North American racing jurisdictions allow some use of at least one NSAID the day before racing. Whether the permissive NSAID regulations and other medication policies contribute to the higher racing fatality rates in North America than most other racing jurisdictions using IFHA rules is debatable. Further complicating the issue, racing regulatory veterinarians, the veterinarians responsible for the prerace examinations have begun to question whether North American NSAID regulations are compromising their examinations by masking clinical signs of inflammation. Currently, an approximate

4-mg/kg dose of phenylbutazone about 24 hours before racing is permitted in North America and conforms to the blood level of lower than 5 mcg/mL on raceday.

The policies and regulations governing the use of corticosteroids, particularly intraarticular corticosteroids, are also under scrutiny. Most racetrack veterinarians believe intraarticular corticosteroids are most effective if used 5 to 10 days before racing (RMA, JAB). Unfortunately, changes in the way races are carded today have made planning for races problematic except for stakes races. Trainers cannot confidently plan for races on a certain date and feel forced to wait until the horse is in a race to perform intraarticular injections, sometimes as little as 2 days before the race. The American Association of Equine Practitioners is recommending that racehorses should not receive intraarticular corticosteroid injection within 5 days of racing. Racing regulatory veterinarians have called for an outright prohibition within 5 to 7 days of racing (RMA). Most corticosteroids are Association of Racing Commissioners International (ARCI) Class 4 drugs, and recent research efforts have been directed toward increasing the sensitivity of drug screening for corticosteroids. Research suggests triamcinolone acetonide and betamethasone have chondroprotective properties when used prudently. On the other hand, one of the most commonly used intraarticular corticosteroids, methylprednisolone acetate, does not fare as well in laboratory studies but is still a preferred intraarticular corticosteroid of many racetrack practitioners because of potency and consistency of clinical response. The pharmacodynamics of intraarticular corticosteroids is just now being studied in horses. With a better understanding of the clinical response to these drugs, combined with advances in laboratory detectability, the way corticosteroids are used may change dramatically within a few years.

Withdrawal time information is not readily available in all jurisdictions for many common therapeutic drugs used for equine lameness. The state-by-state regulation of racing in the United States and the large number of drug-testing laboratories complicates racetrack veterinary practice. Prudence dictates that all veterinarians treating horses intended to race at state-sanctioned racetracks be familiar with the drug testing and medication regulations in that jurisdiction. Resources that may be of use to racetrack veterinarians are the ARCI and the Racing Medication and Testing Consortium (RMTC). Both organizations have websites with information on medication and veterinary practice regulations as well as drug testing.

LAMENESS EXAMINATION

A racetrack clinician has distinct advantages over other practitioners. A racetrack veterinarian is involved intimately in the day-to-day operation of a racing stable and becomes familiar with the normal gait, disposition, and general health care factors of each horse, such as appetite, coat condition, weight, training and racing status, and performance. Numerous examinations can be performed easily if needed. Horses can be examined before and after training to see if lameness worsens or improves.

History

The most important piece of information is the training history. What did the horse do today, yesterday, and the

day before? How far is the horse from racing? When was the last fast work or race? Did any problems occur? Did the horse want to train? Did the horse lug in or out? Did the horse cool out normally? When did the trainer or exercise rider notice a problem? When was the last time the horse was shod? Is the horse receiving any medication? NSAIDs and corticosteroids can easily compromise the veterinarian's ability to properly evaluate lameness (RMA, JAB). The entire veterinary medical history is important for the veterinarian to know, but the past medical history of claiming horses is usually unavailable.

Most fractures occur in horses with a history of a recent hard workout or race. Sometimes lameness may not become apparent until the horse returns to the track several days later, but the injury occurred in the previous workout or race. Humeral stress fractures are the exception, because they usually occur in horses returning to work after not having worked for 45 to 90 days. Horses that lug in (drift toward the inside rail) or lug out (drift toward the outside rail) usually are moving away from the source of pain, but not always. The gallop is a complicated gait, and some horses may drift toward the side of pain while galloping at high speed, perhaps reflecting the lack of power on the affected side (MWR). Most horses in North America finish a race on the right lead. Finishing a race on the left lead may be normal for a horse, but in some horses finishing on the left lead may be a sign of high-speed lameness. A left-lead finish should prompt careful investigation of the left forelimb and right hindlimb as potential sites of lameness (MWR). Many lameness conditions are insidious in onset. Subtle signs, such as a horse that is unusually nervous and prefers to break into the gallop instead of jogging, are easy to overlook. Lameness the day after a shoeing change may implicate a close nail or a drastic change in hoof angle.

The age of the horse is important. Dorsal third metacarpal bone (McIII) disease and other stress-related bone injuries are unusual to diagnose in older horses if they do not have problems at 2 or 3 years of age. Older claiming horses are much more likely to have chronic osteoarthritis (OA), osteochondral fragmentation, or tendon injuries.

Palpation

The physical examination should be routine and complete. Horses are first examined in the stall, where they are comfortable and are more willing to tolerate manipulation. One of us (PJM) feels strongly enough about thorough examination that if trainers want to start with a visual examination while horses are tacked up and proceed directly to injection, they should find another veterinarian. Many lameness conditions are acute, and signs of inflammation are clearly useful. Horses with chronic lameness can be challenging, but long-term association with a horse is of great benefit. Regardless, the examination is the same. Palpation is critically important in evaluating racehorses, possibly the single most important clinical skill a racetrack veterinarian can develop. Very subtle abnormalities or changes from previous examinations can often be the key to developing the most effective diagnostic plan (JAB). With the horse standing squarely, all limbs are palpated for heat, pain, and swelling. During individual flexion of the front fetlock joints and carpi, pain response is important. Pain during carpal flexion almost always indicates a

problem in that region. The clinician should remember that during lower limb flexion tests, joints other than the fetlock are being stressed. If concerned, we flex joints independently if possible. Whenever a pain response is elicited, the same palpation technique should be used to compare the response with that of the contralateral limb. There is considerable individual variation from one horse to another, particularly with more subtle responses. All aspects of the PSBs should be examined with the limb in flexion. SL branches, body, and origin and digital flexor tendons are carefully palpated along the entire length. The dorsal aspect of the McIII is palpated by placing the palm of the hand around the tendons and applying firm finger pressure. The forelimb is then brought forward while elevated, and the dorsal cortex of the McIII is palpated with firm thumb pressure. Careful palpation of the dorsal and palmar aspects of the McIII is important in detecting fracture of this bone (MWC). With the palm of the hand on the dorsal aspect of the McIII, the fingers can be used to palpate the proximal aspect of the SL and each splint bone. Care must be taken when examining the dorsal and palmar metacarpal regions, because the clinician may inadvertently cause pain on the dorsal cortex by examining the palmar aspect of the metacarpal region and vice versa (PJM). Proximal palmar metacarpal pain is important to detect, but false-positive results can occur (MWC). Any suspicious response should be evaluated further with ultrasonography (PJM). The carpus is flexed and the dorsal surfaces of the antebrachiocondylar and middle carpal joints are palpated with thumb pressure. An effort should be made to stretch the joint capsule around the borders of each carpal bone, because stretching often elicits pain if a lesion is present. To evaluate the elbow and shoulder regions, the limb is pulled backward and forward. With the limb extended, a jerking, upward motion sometimes causes pain in horses with humeral stress fractures. The shoulder joint and intertubercular (bicipital) bursa should be palpated with firm digital pressure.

The hands should be run lightly over the back to assess for sore or tense muscles. The lumbar and sacroiliac regions, gluteal muscles, and greater trochanter of the femur should be palpated from each side. Although the process appears hazardous, the gluteal muscles and greater trochanter also should be palpated from behind. If necessary a forelimb can be elevated. Firm pressure should be used to detect gluteal myositis or trochanteric bursitis. Standing behind the horse is the best way to compare effusion of the femoropatellar joints. Each hindlimb should be examined in the standing and flexed positions. The Churchill test should be performed bilaterally (see Chapter 6). A positive response suggests distal hock joint pain. Negative findings on palpation and manipulation do not eliminate a joint from consideration, but positive findings often point to the source of pain causing lameness.

Movement

It is mandatory to observe the horse during the first few steps out of the stall. Then the horse is usually walked down the shed row and back. Occasionally the horse is trotted immediately. If a horse appears "stiff" initially, it is useful to walk the horse a couple of times around the shed row to help discern if the lameness is real or if mild stiffness is a normal characteristic of that horse. This is important

with older horses that may have chronic problems. Horses with painful conditions do not generally warm out of lameness (JAB). It is important to trot the horse at a comfortable speed for the horse, not the handler, and the horse must be trotted far enough to reach an even speed. The head must be free, without allowing the horse to throw the head. Surface is important, and the harder, the better; soft surfaces may hide lameness. The horse is trotted in a straight line and while circling. Trotting the horse in a circle is the best way to differentiate diagonal or ipsilateral lameness (i.e., left forelimb from right or left hindlimb) and exacerbates many lameness conditions. Horses with tibial stress fractures are much worse while circling. Horses with third carpal bone pain and medial foot lameness are worse with the affected limb on the outside of a circle. Horses with lameness of the fetlock joint are usually worse with the affected limb innermost. Although characteristics of lameness while trotting are important, they are subjective.

At times, observing a horse under tack is useful. Often horses with hindlimb lameness are best examined on the racetrack, because many horses do not use themselves behind. Only when horses are absolutely sound in hand is examination at speed warranted, and even then, with the exception of understanding the complaint of the rider, obtaining useful diagnostic information is rare. However, one of us (PJM) likes to examine horses with obscure lameness on the track, under tack at the trot.

The usefulness of flexion or other manipulative tests is debatable. Lameness may be exacerbated, but disagreement exists over what a positive response means. For instance, when performing fetlock flexion, a positive response is common even in horses with lameness unrelated to the fetlock joint (RMA). One of us (PJM) finds fetlock and lower limb flexion tests worthwhile, but not carpal flexion, and finds hindlimb flexion tests nonspecific. One of us (MWC) finds forelimb flexion tests useful but finds all but the lower limb flexion test in the hindlimbs questionable. Finally, one of us finds the carpal flexion test the most specific and accurate flexion test; horses with a positive response generally have carpal region pain, and there are few false-positive results (MWR; see Chapter 8). Hindlimb flexion tests lack specificity (MWR). Each clinician needs to develop a protocol and be consistent.

Diagnostic Analgesia

Diagnostic analgesia is important to localize sources of pain, and sequential, distal-to-proximal, intraarticular, and perineural blocks should be performed. One of us (PJM) feels strongly that shortcuts, such as skipping immediately to a low palmar or plantar block rather than performing a palmar or plantar digital block first, lead only to misdiagnoses. Another (MWC) feels confident in clinical examination and blocks only when unsure of his diagnosis but admits that when a trainer or owner wants a definitive answer, this approach is unacceptable. However, to diagnose proximal plantar metatarsal pain definitively, a block must be performed. Blocking horses with long winter coats can be difficult. For distal McIII or third metatarsal bone (MtIII) bone disease, one of us (MWC) uses specific palmar or plantar metacarpal or metatarsal analgesia. A novel approach is taken to desensitize the distal 50% to 75% of the McIII. Five milliliters of local anesthetic solution are

injected into the nutrient foramen. This block is not specific for bony disease, because the nearby accessory ligament of the deep digital flexor tendon can be affected; however, injury of this ligament is rare.

Whether to clip for intraarticular injections or analgesia is personal preference, but two of us do not clip (MWC, PJM). Although medicating and performing intraarticular analgesia simultaneously is acceptable, one of us (MWC) prefers to wait at least 1 day after blocking to medicate.

Horses may be difficult to handle during analgesic procedures or during intraarticular injections, but usually a lip chain or twitch provides adequate restraint. A good handler must be in control of the horse during the procedure. Gentle, confident, sure hands with painless technique are best (PJM). If sedation is necessary, a combination of 5 mg butorphanol and 200 mg xylazine or 2.5 mg (0.25 mL) detomidine is useful (MWC). However, sedation for diagnostic analgesia should be kept to a minimum. Acepromazine (5 to 10 mg intravenously [IV]) is useful, because the lameness may be exacerbated as a horse trots more quietly. This amount is usually adequate during the analgesic procedure (JAB).

Diagnostic analgesia is often necessary to identify the exact location of pain causing lameness. It is quite useful when two or more limbs or areas are affected. In the forelimb, intraarticular analgesia of the fetlock joint is an excellent and preferred starting point. Palmar disease of the fetlock joint (subchondral bone pain) is common, and if there is a positive response, this block identifies pain in this region. However, if degree of lameness does not change, low palmar or low plantar and palmar metacarpal or plantar metatarsal perineural analgesia (four-point block) should be performed, because subchondral bone pain of the distal aspect of the McIII or the MtIII may not be eliminated using intraarticular analgesia (MWR). Intraarticular analgesia of the fetlock joint will abolish pain associated with an articular fracture of the PSB, pain from which may be abolished using palmar digital analgesia. When the carpus is being blocked, intraarticular analgesia of each joint is useful to determine location of the pain causing lameness. A dorsal approach to the carpus is beneficial to prevent diffusion of local anesthetic solution to the proximal aspect of the SL. It is possible to abolish pain from a fracture of the third carpal bone with subcarpal analgesia. Time of response to intraarticular analgesia is important. A positive response may be seen with an intraarticular problem within minutes. When a positive response to intraarticular analgesia of the middle carpal joint is seen only after 30 minutes, it is important to evaluate the SL. In the hindlimb, a plantar digital nerve block is the preferred starting point.

Approaches and techniques have been well published. A sterile preparation should be performed for intraarticular injection. Gloves are not required but are a personal preference. After injection the limb is bandaged with "foam air" or Vetrap; alcohol and clean cotton bandages are used for the next 12 hours. Concurrent intraarticular medication is often administered but may be more beneficial to the joint if administered 24 hours later.

Diagnostic analgesia is a critical piece of the lameness puzzle. Proper allotment of time is necessary. Consistent interpretation of lameness is essential during the procedure (JAB).

IMAGING CONSIDERATIONS

Routine radiographic images often are supplemented with views looking specifically at problem areas of the TB racehorse. For instance, for the metacarpophalangeal and metatarsophalangeal joints, flexed dorsopalmar or dorso-plantar (DPa, DPl), dorsal 35° distal-palmaro(plantaro) proximal oblique, standard horizontal DPa or DPl, lateromedial (LM), flexed LM, and dorsolateral-palmaro(plantaro) medial oblique and dorsomedial-palmaro(plantaro)lateral oblique images should be considered routine. Additional images of the PSBs may be useful in evaluating fractures of the PSBs or palmar erosions of the McIII or the MtIII. The cassette is placed on the ground and a 45° (or 60°) oblique skyline image of each PSB is obtained (JAB). For the carpus the four standard images and a skyline image of each of the proximal and distal rows of carpal bones are routine. A flexed dorsal 45-degree lateral-palmaromedial oblique image should be considered when evaluating a distal radial carpal bone fracture (JAB).

Scintigraphic examination is important, because TB racehorses frequently develop cortical and subchondral stress-related bone injuries. Horses with obscure or undiagnosed lameness and those suspected of having stress-related bone injuries are candidates for scintigraphic examination. Because complete fracture often results from preexisting stress-related bone injuries in cortical and cancellous bone, horses with signs consistent with pelvic, tibial, humeral, and McIII or MtIII stress fractures should undergo scintigraphic examination before continuing in work. However, interpretation is not always straightforward. False-negative results have been found in horses with preexisting tibial stress fractures (PJM) and false-positive results in those with modeling reflecting changes in work intensity. Therefore experienced interpretation is essential, and follow-up examinations are required if findings do not concur with clinical observations.

For ultrasonographic examination, horses are routinely clipped. Ultrasonographic examination is valuable in diagnosing and staging tendonitis, suspensory desmitis, carpal tenosynovitis, lateral branch superficial digital flexor tendonitis, and other swellings of the pastern, swellings of the medial stifle region, and distal sesamoidean desmitis. Digital ultrasonography is the gold standard (JAB).

SHOEING

Trimming and shoeing of the TB racehorse are extremely important. In many practices, veterinarians are not involved in trimming and shoeing, and decisions often are made exclusively by trainers and farriers. The veterinarian should make every effort to work with the farrier regarding shoeing changes when a musculoskeletal problem renders them necessary (JAB). Because recent evidence has linked catastrophic injury to toe grabs on shoes, now a general trend is to see horses shod with low grabs, or none at all. Toe grabs are thought by many to cause forelimb lameness. Hindlimb toe grabs are often associated with hindlimb injuries on synthetic surfaces. There is virtually no slide of the foot on synthetic surfaces, and toe grabs can be a contributor to lameness (JAB). The rationale for using grabs is questionable, because the forelimbs are propelled by the hindlimbs, and traction on the front feet makes little sense.

Toe grabs may shorten the cranial phase of the stride, prevent forward sliding of the forelimbs, and cause lameness. One of us (MWC) has observed many horses that are stiff and short in front, and by simply removing the grabs and applying Queens plates (aluminum shoes with a low toe grab; Victory Racing Plate Company, Baltimore, Maryland, United States), lameness abates in 2 to 3 days. Steel shoes are a good alternative when horses resume training after a lay off. Training barefoot is often beneficial for horses that continue to develop sole bruises as a result of track surfaces. Training and racing without shoes may be beneficial for horses with distal hindlimb pain such as that caused by subchondral bone injury of the distal aspect of the MtIII (MWR). Lameness associated with toe grabs appears most commonly on dirt tracks with hard bases and cushions of less than 7.5 cm. For racing on dirt the Queens plates or variations are popular, and for turf the Queens plates and Queens XT shoes are required. Turndown shoes have received negative press, but they may be advantageous in horses with low heels. Slight turndowns without toe grabs on hind feet may actually benefit horses with hock and stifle pain. Many lameness problems may be created or exacerbated by poor shoeing, including PSD, tendonitis, and fractures of the PSBs. One of the major problems is shoeing horses with small shoes. Overzealous use of acrylic can cause severe foot lameness. Horses with thin walls are predisposed to nail bind, and those with sheared heels sustain repeated heel bruising. Glue-on shoes may be beneficial in the short term but can be detrimental if used long term. Using a three-quarter shoe is an alternative for bruised quarters. Cut-out or half aluminum plates are useful for a bruised or sore heel. Accurate diagnosis is essential (JAB).

Shoeing for synthetic racing surfaces is a hotly debated issue. In California many trainers are using Queens plates or Queens XT shoes all around for the synthetic surfaces. Rarely are traction devices used behind because of the concern that the natural slide for hindlimbs on dirt is lost on synthetic surfaces when shod with toe grabs, calks, or other traction devices. Many trainers and farriers keep flat or low toes on the hind feet when horses are training and racing on synthetic surfaces. California changed regulations permitting horses to race barefoot on synthetic surfaces. Although this is still fairly unusual, horses perform quite well without shoes on synthetic tracks. More commonly, horses are trained barefoot, especially the hind feet.

INABILITY TO MAKE A DIAGNOSIS

In many horses, despite a methodical and time-consuming approach to diagnostic analgesia, the source of pain cannot be identified (MWC). These horses are referred for additional clinical and scintigraphic examinations (MWC, PJM). Horses with stress-related bone injuries may show few clinical signs, and scintigraphy is the imaging modality of choice. Lameness in young horses in training may be more difficult to diagnose than that in horses that are racing (MWC). Many horses with undiagnosed lameness are confined to at least 6 weeks of walking. The advances of ultrasonography, digital radiography, computed tomography, and magnetic resonance imaging (MRI) have made the inability to make a diagnosis a rarity (JAB).

TEN MOST COMMON LAMENESS CONDITIONS

1. Lameness of the foot
2. Lameness of the metacarpophalangeal or metatarsophalangeal (fetlock) joints
3. Suspensory desmitis
4. Lameness of the carpus
5. Superficial digital flexor tendonitis
6. Tibial stress fractures
7. Distal hock joint pain
8. Myositis
9. Dorsal third metacarpal bone disease
10. Other stress fractures

SPECIFIC LAMENESS CONDITIONS

Lameness of the Foot

The most common cause of lameness in the TB racehorse is foot pain. Horses may be observed in the stall to pile bedding under the feet, presumably to cushion the feet or to change angles. Lameness is often worse with the affected limb on the inside of a circle. Heat at the coronary band and increase in digital pulse amplitude are frequent signs. TB racehorses have little hoof. Many are shod at least monthly, but most are shod more frequently, with thin, lightweight shoes. When shoes are changed frequently, little natural hoof is available with which to work if adjustments are necessary. The tendency is for the farriers to remove too much foot, particularly toward the heel, resulting in low heels. Thin feet have prompted the use of acrylics to augment the hoof wall, but overzealous use may itself result in foot soreness (MWC). Soreness and bruising are common, particularly on the medial quarter, just forward of or at the bar. The center of load distribution for a TB racehorse is medial and palmar to the anatomic center of the foot, close to the medial bar.

Most racehorses react positively to the application of hoof testers because only a thin covering of horn protects the sensitive structures of the foot. Degree of sensitivity to hoof testers is important and is learned through experience. Hoof tester examination is best done when an assistant holds the foot (RMA). Hoof testers can be placed carefully on front and hind feet, and slight differences in positioning make a substantial difference. Left and right feet should be compared at least twice before conclusions are reached. The diagnosis of palmar foot pain can be confirmed readily by selective medial or lateral palmar digital analgesia. Horses with a naturally wide gait, or with carpal pain, bruise the medial quarters and can have concomitant foot pain. Acquired bruises of this nature are difficult to treat in horses with wide gaits without lameness and without managing primary lameness in those with carpal pain. In most horses with foot lameness, diagnosis is made with clinical findings and diagnostic analgesia. If abnormalities of the sole or hoof wall cannot be found, radiographic examination is occasionally necessary (PJM). In most horses without fracture, lameness resolves in 2 to 3 weeks with specific therapy and the administration of NSAIDs.

Bruised Heels or Quarters

Lameness caused by bruised heels or quarters is often mild, and horses usually are kept in training. More often than

not, little heat is associated with a bruised quarter. Mild dilation of one or both digital arteries and hoof tester sensitivity are the most common signs. The best treatment is rest, however. The foot should be examined for any conformational or shoeing faults; sheared heel or unbalanced feet are common causes of bruised quarters. Horses with toed-out conformation often bruise the medial aspect of the heel (MWC). Corrective shoeing is really the only treatment option. Steel shoes distribute force along the hoof wall evenly and can be applied to horses in training but not racing. Bonded shoes can be applied to horses that are racing. If the foot is warm, the horse should stand in ice water, but if the foot is normal in temperature, the horse should stand in a foot tub of hot water with Epsom salts. A poultice of warm, cooked flaxseed or commercially available products such as Animalintex (3M Animal Care Products, St Paul, Minnesota, United States) should be applied. A common practice of applying hoof-hardening agents such as iodine and turpentine should be avoided, because hard hooves bruise easily.

Abscesses

Foot abscesses are a common problem, particularly during the wet seasons. A foot abscess is the most common eventual diagnosis when a horse is found three-legged in the stall in the morning without a recent history of hard work or racing. TBs are prone to foot abscesses because of the manner and frequency of shoeing. Foot abscesses occur most commonly in the medial quarter, where bruising is also most common. Sole abscesses not involving the quarter are uncommon, take more time to resolve, and cause different clinical signs than do abscessed quarters. Although abscesses in the heel or quarter usually are located easily and precisely with hoof testers, a sole abscess can produce a large area of soreness. Identifying the specific area of pain is often difficult.

Horses with foot abscesses are best managed with hot water baths with Epsom salts and poulticing. The longer the horse stands in hot water with Epsom salts, the better. Ideally, the shoe should be removed, and the abscess should be allowed to open naturally. Usually more damage is done to the hoof wall by attempting to open the abscess manually than by allowing it to open naturally. Probing the white line to identify an abscessed area can be worthwhile. Sole abscesses are more likely to require manual opening and debridement than are abscessed quarters. The integrity of the hoof wall needs to be evaluated and preserved, if possible, but wet, infected areas need to be exposed, opened, and dried. Foot abscesses or infections also can originate from grabbed quarters, which occur frequently in horses that stumble out of the starting gate. When grabbed, the hoof wall of the quarter may separate at the heel bulb or quarter, well down the foot. The opened area becomes contaminated with track dirt, and infection can occur several days to weeks after the original injury. Fortunately a pathway for drainage is already present.

Quarter Cracks

Quarter cracks are common for the same reasons as bruising and abscessation. The quarters and heels take continual pounding, particularly in a TB racehorse with poor hoof wall support. Quarter cracks may be caused by poor hoof balance but most commonly result from

innate hoof weakness. Farrier-incurred hoof imbalance can contribute to the development of quarter cracks, but most commonly a single horse in a stable has numerous cracks. Horses with an initial crack are prone to develop subsequent cracks in the same hoof or other hooves. A horse ran successfully with seven quarter crack patches at one time (RMA). If identified early, quarter cracks can be patched readily with acrylic or epoxy resin. The goal is to stabilize the hoof wall and eliminate uneven movement. Mild cracks should be patched if any movement occurs at all. As little patching material as possible should be used to stabilize the hoof wall. If a quarter crack is infected, a drainage path needs to be established. If the quarter crack is infected systemic antibiotics are warranted. An acrylic patch should never be applied until the infection has resolved (JAB). Some epoxy resins are much harder than the natural hoof wall, and trapped infection eventually drains through natural tissues rather than the patch. The incidence of quarter cracks is markedly reduced on synthetic surfaces (JAB).

Osteoarthritis of the Distal Interphalangeal Joint

Most lameness conditions of the foot seen in other sports horses also occur in racing TBs. Considerable controversy exists regarding the frequency of osteoarthritis (OA) of the distal interphalangeal (DIP) joint. Some veterinarians diagnose the problem regularly, whereas others never recognize it. In our experience, OA of the DIP joint is uncommon. Effusion is the most common clinical sign. Osteophytes may be seen on the extensor process of the distal phalanx. Frequently, horses with bilateral OA of the DIP joint have poor performance rather than overt lameness, and lameness is worse at the end of a race (MWC).

Navicular Syndrome

Navicular disease and navicular bursitis are unusual or rare conditions in the TB racehorse (PJM). Lameness can be localized using palmar digital analgesia, but most often horses have bruises, cracks, and abscesses, and those with navicular syndrome are unusual. One of us (MWC) diagnoses navicular bursitis commonly. Rarely, fractures of the navicular bone, bipartite formation, or other anomalous conditions of the navicular bone can occur in young TBs, either in the forelimbs or hindlimbs. Successful management of this type of palmar foot pain has been achieved by injecting the digital cushion with orgotein (Palosein) and Sarapin and methylprednisolone acetate, applying a bar shoe, increasing heel angle, and giving NSAIDs. Intraarticular injection of the DIP joint with hyaluronan and corticosteroids affects numerous structures in the foot and improves the condition of horses with navicular syndrome or OA of the DIP joint.

Distal Phalanx Fractures

Fractures of the distal phalanx occur occasionally. Most fractures are nonarticular palmar process (wing) fractures, and horses do well with the application of a bar shoe. Articular wing fractures are more serious. Extensor process fragments are rare and can be removed arthroscopically.

Palmar digital neurectomy is permitted in most racing jurisdictions, but it must be reported to the race office. Indications for neurectomy are few, but occasionally a horse with a distal phalangeal fracture and chronic pain is

a candidate. Occasionally, palmar digital neurectomy is performed in horses with recurrent quarter cracks to eliminate pain, but the procedure does nothing to solve the original problem. Surgical neurectomy should be performed because percutaneous techniques are often ineffective.

Lameness of the Fetlock Joint

The metacarpophalangeal or metatarsophalangeal (fetlock) joint, carpus, and tarsus are the most important joints associated with lameness in racing TBs, especially the fetlock joints. Clinical findings of fetlock joint lameness usually include effusion, heat, a positive response to flexion, and elimination of lameness using intraarticular analgesia. However, in some horses with subchondral bone pain, clinical signs such as effusion are often lacking, and perineural blocks are most effective. The most common lameness conditions of the fetlock can be divided into four categories: synovitis, distal palmar McIII or MtIII disease, fractures, and OA.

Synovitis

Fetlock joint pain associated with effusion, pain on joint manipulation, a positive response to a distal limb flexion test, and moderate lameness is common, but horses generally respond well to intraarticular treatment with hyaluronan and corticosteroids (repeated if necessary), combined with systemic treatment with polysulfated glycosaminoglycans (PSGAGs). Intravenous hyaluronan may be useful in these horses. However, recurrence of clinical signs indicates that the horse should be removed from training, because continued training may result in chronic OA (MWC). The use of autologous conditioned serum (interleukin-1 receptor antagonist, IRAP) has gained popularity for management of synovitis (JAB).

An increase in forelimb tenosynovitis of the digital flexor tendon sheaths (DFTs) has been noted in horses trained and raced on synthetic surfaces. Lameness is acute. The DFTS is distended and warm to palpation, and there is a marked response to lower limb flexion. Ultrasonographic and radiographic examinations are often normal and unrewarding. These horses typically become sound in 7 to 10 days with the administration of NSAIDs, walking, and the application of a topical poultice (JAB). Firing and blistering may be useful.

Distal Third Metacarpal or Metatarsal Bone Disease

Stress and maladaptive or nonadaptive remodeling, a form of stress-related bone injury, of the distal aspects of the McIII and the MtIII is a common cause of lameness. During training and racing, these areas undergo considerable modeling and remodeling, change shape, and are at risk to develop fracture and cartilage damage. Scintigraphic examination reveals focal areas of increased radiopharmaceutical uptake (IRU) and is the imaging modality of choice for diagnosis, because radiographs are often negative. Ultimately, damage to the distal aspect of the McIII and the MtIII leads to OA and fracture. Early in the course of the disease pain originates from subchondral bone, without effusion or heat. However, intraarticular analgesia is usually effective in partially eliminating pain. Perineural analgesia of the palmar or plantar and palmar metacarpal or plantar metatarsal nerves (low four-point block) or a modification

of the diagnostic technique is usually quite successful in abolishing pain. In a hindlimb the lateral plantar metatarsal nerve can be blocked independently of the other three nerves in the conventional low four-point block; in most horses improvement is noted, or a horse will then show contralateral hindlimb lameness. Often contralateral limb lameness is quite prominent and lameness grade can be 1 or 2 degrees higher than in the original limb (MWR). If lateral plantar analgesia produces only partial improvement or if no improvement is noted, the conventional low four-point technique should then be completed. In some horses all fetlock joints are affected simultaneously, and the horse appears sore all over. This disease is often referred to as "bone bruising" but is a form of chronic, stress-related bone injury characterized by the development of dense, painful sclerotic bone, rather than acute, subchondral bone injury from a single-event form of trauma. Distal McIII or MtIII disease is so prevalent that some veterinarians first perform intraarticular analgesia of the fetlock joint rather than beginning with palmar or plantar digital analgesia. As the disease progresses, radiological changes can include flattening of the distal palmar aspect of the McIII or the MtIII, increased radiopacity and radiolucency, and, when severe, large areas of subchondral lucency of the McIII or the MtIII. A form of severe flattening of the distal palmar aspect of the McIII has been recognized and may result in severe OA by the end of the 3-year-old year (MWC). Negative radiological findings do not eliminate this disease as a source of pain, and scintigraphy is more sensitive for its detection. Areas of IRU can represent subchondral bone damage from nonadaptive remodeling or fracture, and a combination of imaging modalities is necessary to differentiate these conditions. Increased radiopacity representing sclerosis of the distal palmar or plantar aspects of the McIII and the MtIII may be visible. Interpretation of sclerosis is subjective and should correlate to scintigraphic findings and clinical signs. Subtle fracture lines do occur in the subchondral bone plate of the distal condyle of the McIII and the MtIII. These become evident on successive radiographs. Surgical fixation of a visible fracture in the subchondral bone plate is the preferred treatment (JAB). Rest, a minimum of 4 months, to allow healing of sclerotic subchondral bone is recommended in horses without fracture, the most common situation. Bisphosphonate therapy has become popular, but there is little evidence to date to support the use of bisphosphonates unless administered in horses that are resting or in a reduced training program (see Chapter 42, page 490). One author (MWR) has used subchondral forage in two TBs with unilateral hindlimb lameness as a result of subchondral bone injury, and although both horses returned to racing, one developed recurrent lameness as a result of the same condition. Recurrence of lameness is a common problem in 40% to 50% of horses with conservative management.

Osteochondral Fragmentation

Osteochondral fragments (chip fractures) of the proximal, dorsal aspect of the proximal phalanx are common in TB racehorses. Fragments are more often medial than lateral, but they can occur biaxially and bilaterally. Fragments are more common in forelimbs but do occur in hindlimbs as well. Often disease of the fetlock joint occurs before fragments are recognized. Subtle radiological changes in the

silhouette of the dorsal rim of the proximal phalanx are important and indicate that this area is experiencing stress. The distal dorsal aspect of the McIII at the joint capsule attachment can be injured at the same time that chip fractures are seen.

Once fractures are recognized, arthroscopic surgery should be performed. After surgery the horse can be back in training in as little as 6 weeks if cartilage damage is minimal. Horses with small fragments can be managed conservatively using local ice therapy, NSAIDs, and a reduction in exercise intensity. Inflammation (effusion) subsides within 7 to 10 days, and training can be resumed. Small osteochondral fragments appear to demineralize and no longer irritate the joint. If inflammation and lameness recur, the horse should be taken out of training, and surgery is recommended. Intraarticular injection of corticosteroids and hyaluronan is one option and is effective at reducing inflammation, but if training and racing continue, deep scoring of the articular cartilage of the distal aspect of the McIII occurs and leads to OA. If the goal is long-term racing, surgery should always be recommended.

Osteoarthritis

OA is a common problem and usually is associated with fractures of the proximal phalanx or palmar or plantar McIII or MtIII disease, but it can develop as a primary condition. Arthroscopic examination often reveals considerable articular cartilage scoring and thinning, or complete erosions through the articular cartilage, without any evidence of an associated fracture. Because OA is chronic and cartilage cannot regenerate, the disease must be identified early so preventative measures can be taken. Judicious use of NSAIDs and intramuscular PSGAGs is the best long-term treatment for OA of the fetlock joint. If present, fractures need to be repaired or fragments removed. Young horses should be taken out of training and allowed to mature. Immature horses are particularly prone to overextension injury of the fetlock joint. Some horses may require PSGAGs throughout the racing career. Oral supplements may be beneficial, but intramuscular administration is best. Repeated use of intraarticular corticosteroids exacerbates chronic OA, but whether this is a direct result of the medication or simply allowing a horse to continue in training and racing is unknown. Unfortunately, heat, effusion, positive response to flexion, and lameness resulting from OA need to be treated, because horses are expected to perform. Intraarticular injections are unavoidable, and a combination of hyaluronan and corticosteroids is preferred (RMA). Horses with recurrent synovitis may need additional injections in combination with 2 to 3 weeks of rest (MWC). In spite of information to the contrary, methylprednisolone acetate is the drug of choice, because if used prudently at well spaced intervals, the drug is preferable to repeated injections of shorter-acting corticosteroids (RMA). Intraarticular injections of PSGAGs every 2 weeks are beneficial in horses with chronic OA (PJM). IRAP therapy is gaining popularity for treatment of OA in the fetlock joint. It should be used in conjunction with rest or as a postoperative treatment for better efficacy (JAB).

Other Conditions

Distal McIII or MtIII condylar fractures, PSB fractures, sesamoiditis, and proximal phalangeal fractures are discussed in

Chapters 35, 36, and 42. Distal McIII or MtIII condylar fractures often result from maladaptive or nonadaptive remodeling and may be more common in certain racetrack practices than others. One of us (PJM) includes these fractures as a top 10 lameness condition. Prognosis is much better in horses with incomplete fractures, with or without surgery. One author (PJM) recommends surgery in horses with fractures longer than 4 to 5 cm above the joint surface. Surgical fixation may yield a better long-term prognosis than conservative management in horses with short condylar fractures of the McIII and the MtIII since quality of healing may be better and recurrence of the injury less (MWR).

Lameness of the Carpus

The carpus is similar to the fetlock joint in several ways. The third carpal bone undergoes considerable modeling and remodeling with associated subchondral bone pain, similar to the distal palmar or plantar aspect of the McIII or MtIII. Fractures and OA are often the end-stage result of this process of stress-related bone injury. The response of the third carpal bone to stress-related bone injury is similar to that of cortical bone.

Nonadaptive Remodeling of the Third Carpal and Radial Carpal Bones

The third carpal bone and other carpal bones such as the radial carpal bone become sclerotic (model) to withstand the stress of training and racing. The change in the third carpal bone is seen on a skyline radiograph as increased radiopacity of the radial fossa. The mere presence of increased radiopacity does not establish a diagnosis because a certain amount of increased radiopacity reflects a normal, adaptive response. At what point the sclerotic process becomes pathological is not known. Diagnostic analgesia should be used to establish the authentic source of pain. Sclerotic bone eventually becomes painful if the condition of stress remodeling becomes pathological, called *maladaptive or nonadaptive remodeling*. If training and racing continue, bone loss, lysis, or fracture occurs. Third carpal bone subchondral bone pain is common, particularly in young horses, but because pain involves bone, no treatment other than reducing training and racing intensity is available.

Diagnosis of third carpal bone subchondral bone pain can be challenging, because many young horses do not develop effusion. Heat may be present over the dorsal aspect of the carpus, and horses move wide and tend to abduct the limb during advancement (MWC). Response to flexion varies, but in horses with subchondral bone pain, response is often negative. Diagnostic analgesia is essential for diagnosis. Careful interpretation of the results of diagnostic analgesia is necessary because inadvertently blocking the proximal palmar metacarpal region with middle carpal analgesia and vice versa is easy (MWC). The middle carpal and antebrachiohumeral joints always should be blocked separately. Radiological changes of increased radiopacity and later radiolucency can be seen with good-quality skyline images, but they are missed easily with poorly positioned and exposed images. To assess radiographic exposure, the veterinarian should evaluate the second and fourth carpal bones. These bones rarely have alterations in trabecular pattern, and both bones should be clearly visible on the skyline image. Scintigraphy is an excellent tool with which to diagnose stress-related bone injuries of the third carpal

bone and other carpal bones, and although not needed in many horses, scintigraphy assists in early diagnosis and helps convince skeptical trainers and owners. Sclerosis of the third carpal bone changes the mechanical properties of bone, and sclerotic bone is brittle and at risk of fracturing. Few osteochondral fragments or small (chip) or large (slab) fractures of the third carpal bone occur in normal bone. At the time of arthroscopic surgery to repair a third carpal bone frontal slab fracture, a wedge-shaped piece of sclerotic and often necrotic bone often can be found between the fracture fragment and parent third carpal bone.

Once painful sclerosis of the third carpal bone develops, treatment is difficult. Rest may not help remodel dense bone, so prevention is important. The training programs of young TBs with evidence of third carpal bone sclerosis should be modified, but trainers are often unwilling. Although little evidence supports using isoxsuprine or aspirin to improve blood flow, some veterinarians prescribe these medications. Bisphosphonate therapy has become popular but there is little conclusive evidence regarding efficacy. Extracorporeal shock wave therapy (ESWT) is useful in treating horses with third carpal bone remodeling and pain. The benefits of therapy will be achieved only in conjunction with rest or a substantial reduction in training. There will be no radiological changes; however, there will be a reduction in pain when full training resumes (JAB).

Carpal Fractures

Osteochondral fragmentation of the carpus is a common problem. Clinical signs are unique for each fracture type, and radiographic examination is most important. Horses with distal radial carpal bone fractures exhibit pain on direct palpation of the fracture site and often have effusion of the middle carpal joint. Horses with third carpal bone pain and fractures are unwilling to rock on the limb, evaluated by picking up the contralateral limb and forcing the horse to rock on the affected limb by putting side-to-side pressure against the horse's body. Horses with distal, lateral radius fractures generally have pain on direct palpation. Horses with proximal intermediate carpal and radial carpal bone fractures may be surprisingly lame, without obvious palpable abnormalities.

A rare fracture, but one to keep in mind, is a sagittal fracture of the proximal aspect of the intermediate carpal bone (MWC). Horses train and race but come back to the barn obviously lame (grade 3 of 5). When walking and jogging, they exhibit a stiff-legged gait and obvious abduction during advancement. Horses respond positively to carpal flexion, and lameness is abolished using antebrachiocarpal analgesia. Intraarticular treatment does not improve lameness. The skyline image of the proximal row of carpal bones is mandatory for diagnosis, because fractures will be missed on other views. Early arthroscopic surgery is recommended, because OA can develop if horses are continued in work with a fracture.

Arthroscopic surgery has improved the management of horses with carpal joint lameness greatly. Removal of small osteochondral fragments and repair of large fragments substantially reduces the severity of OA. PSGAGs can be useful in limiting the development of OA, particularly if pain is originating from the third carpal bone. After surgery in horses with carpal osteochondral fragmentation, one of us (MWC) recommends hyaluronan injection 2 to 3 weeks

later. Horses with fractures of the middle carpal joint need additional rest compared with horses with antebrachiocarpal joint fractures (MWC). One of us (PJM) prefers to manage horses with incomplete or nondisplaced third carpal bone slab fractures conservatively by giving 60 days of rest and reevaluating the horse. The prognosis for TB racehorses with displaced third carpal bone slab fractures even with surgery is only guarded. Horses with fractures extending into the weight-bearing surface of carpal bones more than 0.5 cm have a poor prognosis. Horses with recurrent and chronic OA appear to benefit from topical blisters and 3 or more months of rest.

Osteoarthritis

In young horses with early signs of OA, rest is recommended. In horses with chronic OA that are able to race, intraarticular injection of a combination of hyaluronan and PSGAG produces better results than does injection of either product alone (MWC). In horses with mild or moderate lameness, intraarticular injection of hyaluronan and triamcinolone acetonide a minimum of 5 to 7 days before racing (depending on racing commission rules) decreases clinical signs for 6 to 8 weeks. Most horses exhibiting carpal lameness appear to benefit from the intramuscular administration of PSGAG once every 4 days for seven or eight treatments, and intravenous injection of hyaluronan appears beneficial before racing.

Rest should be recommended for young horses with early OA even though recurrence of signs is common. NSAIDs are useful in managing pain in horses with OA of the carpus.

Intercarpal Ligament Damage

Because the complex carpal joint is highly dynamic and moveable, fractures and soft tissue damage can lead to OA. Although fractures are more common, injury of the medial palmar intercarpal ligament has been recognized (see Chapter 38).

Another rarely seen lameness of the carpus is related to an osteochondroma of the distal aspect of the radius (see Chapter 75). Rarely, exostoses of the caudal perimeter of the distal radial physes are seen. These horses are acutely lame after exercise and sound within a few hours. Marked carpal sheath swelling and resistance to carpal flexion are usually obvious. Radiologically, there is an osteochondroma proximal and medial to the distal radial physis. There is usually marked carpal sheath effusion seen on ultrasonographic examination. The osteochondroma structure and a lesion in the DDFT are often evident. Surgery to remove the osteochondroma or exostoses is the treatment of choice. Prognosis depends on the degree of damage to the DDFT and the tendency for the osteochondroma to reappear (JAB).

Suspensory Desmitis

Proximal Suspensory Desmitis

Suspensory desmitis is a very important cause of lameness in the TB racehorse and previously has been underestimated. Suspensory desmitis is much more common in forelimbs than in hindlimbs (PJM). Hindlimb PSD is difficult to diagnose because horses have a stiff, hopping-type gait similar to that in horses with tibial stress fractures, and

heat and swelling are unusual (MWC). Lameness in horses with forelimb PSD is similar to that in horses with carpal disease. Horses travel wide, with a shortened cranial phase of the stride, and are worse with the limb on the outside of a circle. Conformational faults such as offset knees and upright pasterns and fetlock joints predispose horses to PSD. PSD is most commonly a 2-year-old lameness condition, perhaps caused by immaturity, and can be diagnosed by manual palpation in some horses, but that is the exception rather than the rule (MWC). An increase in occurrence of PSD has been noted in horses that race and train on synthetic surfaces. This may be related to the inability of the foot to slide, causing increased stress on the SL (JAB). More often, horses with PSD require diagnostic analgesia, and one author (RMA) uses the lateral palmar block, the site for which is just below the accessory carpal bone. With the lateral palmar block it is unlikely to inadvertently cause analgesia of the carpometacarpal and middle carpal joints. In many horses, lameness thought to originate from PSD, after a positive response to high palmar analgesia, was later found to originate from the carpus (MWC).

Considerable variation occurs in the ultrasonographic appearance of the proximal aspect of normal and diseased SLs. Overt tears are easy to diagnose. Chronic tears have an abnormal ultrasonographic appearance despite absence of clinical signs (JAB). Hypoechoic areas can be identified in sound horses. Furthermore, bony pathological conditions of the proximal, palmar aspect of the McIII can be seen in horses without obvious tearing of the SL. Avulsion fractures of the McIII are diagnosed in horses that develop acute, severe lameness abolished by lateral palmar analgesia. Scintigraphy is the best way to diagnose bony injury of the proximal aspect of the McIII in horses without ultrasonographic evidence of PSD and negative radiological findings. Avulsion fracture of the McIII is associated with focal, intense IRU, but many horses have diffuse IRU of the proximal aspect of the McIII. Whether these horses have chronic avulsion injury or whether this represents stress reaction or other injury of the proximal aspect of the McIII is unknown. Regardless, horses with bony injury of the proximal, palmar aspect of the McIII have a good prognosis if given a minimum of 120 days of rest. Horses with PSD often can be managed and allowed to continue racing. Local infiltration with corticosteroids or other products is of questionable benefit, and systemic therapy is more effective and rewarding (RMA). Others disagree and recommend local injection with triamcinolone acetonide in horses with mild PSD (PJM). The combination of Sarapin, methylprednisolone acetate, and in some horses Palosein has been successful, and 2-year-old horses may never take another lame step (MWC). Systemic corticosteroids and NSAIDs reduce inflammation enough to relieve the lameness. Where regulations permit, phenylbutazone and triamcinolone acetonide (12 to 18 mg intramuscularly) can be administered 3 to 5 days before racing. A good alternative is two Naquasone (a combination of the diuretic trichlormethiazide [200 mg] and dexamethasone [5 mg]) 48 hours before racing, if permitted by the rules of racing. Triamcinolone acetonide lasts longer, but Naquasone contains a diuretic that is also useful for reducing swelling. An ice boot or an ice tub is beneficial. Platelet-rich plasma (PRP) may be beneficial for treating horses with lesions of the SL. A single treatment or treatment in combination

with autogenous stem cells appears promising, when combined with removal from training for 4 to 6 months. Prognosis is good. ESWT is also useful in horses with PSD. Repeated treatments every 10 days for 6 weeks is ideal. The horse should be jogging during the treatment (JAB).

Horses in which lameness is mild when trotted in hand or even under tack but that refuse to give a full effort toward the end of a race should be given rest.

Corrective shoeing can make a difference in horses with PSD. In fact, PSD may be secondary to lameness of the foot (MWC). The toe should be shortened, and the shoe should have only minimal toe grabs. Horses with PSD do not develop catastrophic disruption of the suspensory apparatus but return from a race sore.

Suspensory Branch Desmitis

Suspensory branch desmitis is a different situation and can easily lead to catastrophic breakdown if horses are managed improperly. Early detection is critical because suspensory branch desmitis is a predisposing factor for condylar fractures of the McIII. If there is any detectable change or swelling of a suspensory branch, an ultrasonographic examination should be performed. Subtle clinical changes can predispose the horse to catastrophic breakdown and must be identified early (JAB). Management of suspensory branch desmitis with infiltration of corticosteroids in a TB racehorse is a high-risk treatment, with no therapeutic benefit to the horse. Systemic antiinflammatory therapy similar to the approach described for PSD is useful for horses with suspensory branch desmitis, but the horse should not be raced if the SL remains hot and painful. Suspensory branch desmitis is a dangerous injury.

In horses with suspensory branch desmitis the splint bones should be evaluated carefully. Radiographs should be obtained to check for fracture, flaring, or thickening of the second and fourth metacarpal bones. A clear relationship exists between suspensory branch desmitis and pathological conditions of the splint bone. Splint ostectomy is recommended in horses with fractured, flared, or thickened splint bones, not just in those with fracture.

Midbody Desmitis

Horses with midbody desmitis can be managed similarly to those with PSD, but if desmitis extends distally into the branches, the risk of catastrophic breakdown exists. Horses with suspensory desmitis may benefit from rest (45 to 120 days) and blistering (PJM).

Bucked Shins: Dorsal Metacarpal Disease

Bucked shins or dorsal metacarpal disease (periostitis) is common but readily manageable (see Chapter 102). This condition is simply the mismatching of exercise with modeling and remodeling of the McIII necessary for the bone to withstand the rigors of training and racing. Bucked shins are most commonly seen in young horses early in training. The simplest and best treatment is to modify the training program to match the horse. With bucked shins, horses are usually only mildly lame after exercise, unilaterally or bilaterally (PJM). Bucked shins are common in young horses with other primary lameness conditions, particularly of the hindlimbs (MWC). Heat and pain over the dorsal cortex of the McIII are commonly found, but care must be taken not to place pressure on the palmar metacarpal structures while

palpating the dorsal cortex (PJM). One of us (MWC) feels that careful palpation of the palmar cortex is useful in identifying McIII disease. Clinical signs are usually sufficient for diagnosis, but low or high palmar nerve blocks, infiltration of the nutrient foramen of the McIII, or local infiltration of local anesthetic solution occasionally is required (MWC). Radiographs reveal a typical modeling response, but in some horses with fracture, computed or digital radiographs should be obtained, because fractures may be missed on conventional films (PJM). Scintigraphic examination can be useful, mostly in horses with dorsal cortical fracture (MWC).

Great strides have been made in changing training techniques to manage TB racehorses with bucked shins (see Chapter 102). This requires close monitoring of the dorsal cortex of the McIII. Overall, the incidence of authentic dorsal cortical fractures has decreased greatly. Although all trainers have horses with bucked shins, those that still have major problems train in the old-fashioned style. There is a noticeable reduction of bucked shins in horses racing and training on synthetic surfaces (JAB).

Once inflammation is noticed, ice, NSAIDs, and topical cooling muds, such as Uptite poultice (Uptite, Lawrence, Massachusetts, United States), are often all that is necessary if training intensity is reduced and modified. Once the periosteum becomes hot, thickened, and sore over a large portion of the dorsal cortex of the McIII, modifying training is usually too late. Training should be stopped, and when necessary thermocautery may still be the best treatment, once inflammation has subsided (RMA, PJM, MWC). When done properly thermocautery is humane and effective. An old-time racetrack practitioner was asked a few years ago if he still fires horses, and if so, why? His response was simple: "I can tell you in two words: It works." The real problem with thermocautery is perception. Most persons who adamantly are opposed to thermocautery generally have no experience with the procedure. Regardless, alternative treatments are available, but none in one author's opinion work as well as thermocautery (RMA). All treatments require extended periods of rest or light training. Others prefer a relatively new technique called *periosteal scratching*. A 16-gauge needle is used to create linear incisions of the periosteum using aseptic technique. This procedure, as with thermocautery, is combined with rest and is done after the inflammation has subsided (PJM). Prognosis after periosteal scratching is estimated to be 70% (MWC). ESWT is an effective therapy for bucked shins. The success of treatment relies on training modification. Treatment is performed every 10 days for 3 to 5 treatments. During that time the horse should only walk and jog (JAB).

Bucked shins can progress to dorsal cortical (stress) fracture if horses with periostitis are forced to continue training. Stress fractures occur most commonly on the dorsolateral aspect of the McIII, but those located in the distal third to distal fourth of the McIII are most problematic. Fractures in this location under the extensor tendons can be difficult to palpate, but they may be extensive.

Horses with bucked shins should not be lame at the jog 1 to 2 days after the last workout, but if lameness persists, a dorsal cortical fracture should be suspected. Radiographs should be obtained. Success in treating horses with dorsal cortical fracture relates directly to the duration of fracture. Horses with acute fractures are treated more easily than

those with chronic fractures. In horses with acute fractures, rest, with or without thermocautery, is successful. Chronic dorsal cortical fractures are essentially nonunions and heal slowly or not at all and require surgery. Cortical drilling (forage, osteostixis) using numerous small-diameter holes drilled across the fracture line is effective and in one author's opinion is the treatment of choice (RMA). Rarely a cortex bone screw placed in lag fashion or as a positional screw is needed. The question of whether compression using lag screw technique is necessary or if screws are best placed as set or positional screws remains unanswered. Implants must be removed before training begins. ESWT in combination with rest appears promising for the management of dorsal cortical fractures of the McIII (MWR).

Superficial Digital Flexor Tendonitis

Superficial digital flexor tendonitis usually is advanced before lameness is observed and diagnosis is made. Lameness is one of the last clinical signs observed. Prognosis for racing is poor when lameness is present (JAB). Superficial digital flexor tendonitis is usually a career-threatening or career-ending injury, and estimates indicate that superficial digital flexor tendonitis is the single most common injury ending a TB racehorse's career. However, many horses with superficial digital flexor tendonitis return to racing or, on occasion, race through the injury. One author (RMA) feels strongly that local infiltration of corticosteroids and continued racing are contraindicated. Intralesional injection of corticosteroids can cause tendon necrosis and result in complete rupture of the superficial digital flexor tendon (SDFT). Some horses may be able to race after treatment with systemic corticosteroids, NSAIDs, and ice therapy. The SDFT will set up on occasion, but that is certainly an exception, and horses fall in value.

Recognizing superficial digital flexor tendonitis before overt fiber tearing occurs has distinct advantages. To recognize tendonitis early, horses must be monitored closely, and ultrasonographic examination must be performed at the earliest indication of inflammation. Heat and swelling are early clinical signs but may not indicate necessarily that the tendon is involved, because peritendinous injury can cause similar signs. *The key is pain on palpation of the suspect tendon.* Pain, even without obvious heat or swelling, is an important clinical finding. Ultrasonographic examination must include cross-sectional area measurements, because subtle enlargement of the SDFT precedes fiber tearing. Once early superficial digital flexor tendonitis has been recognized, horses should be given rest, or at least the training intensity should be reduced.

One author (RMA) prefers to manage horses with core lesions of the SDFT with tenoplasty (tendon splitting). The surgery can be done with the horse standing and is inexpensive, and aftercare is minimal. To perform tendon splitting, a core lesion must be present, and the earlier the procedure is done, the better. A double-edged tenotome is used. The tendon fibers are split longitudinally with five rows of about 15 percutaneous stab incisions each. After surgery horses are surprisingly sound. Horses with superficial tearing along the edge of a SDFT have a poor prognosis with any treatment and may be the only candidates for peritendinous injection of corticosteroids, provided the horse is removed from training and rested. PRP and stem cell therapy appear promising in treating SDFT core and

peripheral lesions. Ongoing research is needed to determine long-term efficacy. Lesions are typically resolved ultrasonographically at 60 days. Rehabilitation is critical to success, and the horse should not have a saddle on its back for 8 to 10 months. ESWT has been unrewarding in getting horses back to racing after an acute tendon injury. It does, however, have some merit in treating horses with chronic tendonitis (JAB). One author prefers the use of surgical management (MWR; see Chapter 69). A combination of desmotomy of the accessory ligament of the superficial flexor muscle (superior check ligament) and tenoplasty is recommended. Prognosis in the TB racehorse, however, is no higher than 50% to 60%, and recurrence of tendonitis is common.

Horses with superficial digital flexor tendonitis should have as much time off as possible. However, if owners and trainers are unwilling to give 6 to 8 months of rest before the horse returns to training, any treatment is a waste of time. One of us (PJM) has stopped recommending any form of surgery or injections and simply recommends walking rest for 4 to 16 weeks. A blister is applied at least twice, and tendon healing is monitored with ultrasonography. Even with this approach, recurrence rate is 60% to 80%. The trainer plays a major role in rehabilitating horses with superficial digital flexor tendonitis. Those that are successful give the horse the most time off and are patient getting the horse fit before starting hard work.

Tibial Stress Fractures

Tibial stress fractures are the most common cause of acute, pronounced, unilateral hindlimb lameness in the TB racehorse. Lameness from tibial stress fractures usually is recognized after a hard workout or after breaking from the gate. Lameness can be severe, and the horse may not bear weight on the limb. Tibial stress fractures are usually unilateral, but bilateral fractures can cause unusual hindlimb lameness (PJM). Similar to humeral stress fractures, tibial stress fractures can occur after a horse has had 60 to 90 days of training, often after a period of rest for an unrelated cause. Tibial stress fractures can occur anytime during training and racing, and the association between a layup period and the early development of a tibial stress fracture is not as well established as for horses with humeral stress fractures (MWR). Two of us (RMA, PJM) do not find manual palpation of the tibia useful diagnostically, but one of us (MWC) finds deep palpation and tibial percussion helpful. Scintigraphy is the diagnostic modality of choice. Less than 50% of horses diagnosed with tibial stress fractures using scintigraphy have radiologically apparent fractures, even if follow-up examination is performed after 2 weeks. If scintigraphy is unavailable, even small areas of periosteal, endosteal, or cortical change should be considered important, if clinical signs suggest tibial stress fracture. Tibial stress fractures are located most commonly on the caudolateral cortex, proximally or midshaft, but can occur caudolaterally and caudomedially distally. Bilateral tibial stress fractures are occasionally seen, even in horses with unilateral hindlimb lameness. One of us (PJM) has examined a number of horses with clinical signs consistent with tibial stress fracture but in which scintigraphic examination findings were negative. Horses returned to the track and developed complete tibial fractures. Now this author (PJM) recommends reexamination in 3 weeks. False-negative

results are unusual in horses with stress-related bone injuries unless fractures are located medially and only lateral scintigraphic images are obtained (MWR). Horses that are trained on synthetic surfaces with hindlimb toe grabs appear to have an increased incidence of tibial stress fractures. Whether synthetic surfaces increase the incidence of tibial stress fracture as compared with dirt surfaces is unclear and will not be answered without clinical research (JAB). A recent trend is for practitioners to take digital radiographic images of a tibia in a TB racehorse suspected of having a tibial stress fracture in lieu of obtaining a scintigraphic examination. There are many normal irregularities of the cranial tibial cortex and care must be taken not to make an erroneous diagnosis; the practitioner should keep in mind the common distribution of tibial stress fractures (see above). One of the authors (MWR) has never recognized an authentic tibial stress fracture involving the cranial cortex.

Horses with tibial stress fractures are given 90 to 120 days of rest. The prognosis is excellent. The crus is well muscled and has a good blood supply, and callus formation of the tibia does not interfere with nearby structures. Complications develop when horses have spiral fractures and severe lameness or when horses with unrecognized tibial stress fractures are trained or raced. Catastrophic failure can result. Tibial stress fractures can recur if horses are given inadequate time for healing, but this is otherwise unusual.

Some horses with only mild lameness at the time of initial diagnosis and in which lameness rapidly resolved can be kept in light work. In these horses scintigraphic examination reveals mild IRU, and radiographs are negative. Horses are given a minimum of 60 days without hard work, but if lameness recurs, additional rest for 90 to 120 days is recommended. Aspirin at 60 grains orally (PO) sid is thought to be of benefit during rest (JAB). When the horse becomes sound, light training may begin (JAB).

Tibial stress fractures were misdiagnosed as stifle lameness for years at some racetracks, and the same error is still made today. Even with the introduction of high-quality nonportable radiography equipment at referral centers, the diagnosis of a tibial stress fracture has been difficult to make because radiographs are often negative and clinicians have to isolate pain, a difficult task in many TB racehorses. Scintigraphy has taught us that tibial stress fracture is an important and frequent cause of hindlimb lameness in TB racehorses.

Distal Hock Joint Pain

Distal hock joint pain, or distal tarsitis, is a common cause of hindlimb lameness. One of us (MWC) feels strongly that the hock joint is the most important articular structure in equine locomotion. Compensatory lameness caused by primary distal hock joint pain is important. The skeleton of the TB foundation sire Eclipse at the Racing Museum in Newmarket and the skeleton from an extinct breed from the La Brea Tar Pits in Southern California reveal extensive osteoarthritic changes. Radiological changes in the tarso-metatarsal joint of young horses are common and can be found in yearlings before training begins. The importance of osteophyte formation involving the dorsal proximal aspect of the MtIII, often called *juvenile spavin*, is difficult to evaluate without signs of lameness.

Horses with distal hock joint pain have a typical gait. The hindlimbs travel close together and may even cross midline. Horses with bilateral lameness may not show overt lameness, but they are observed to be not right behind (PJM). This has been described as a “bicycling” gait because the hindlimbs appear to mimic the action of peddling a bicycle (JAB). However, this gait is not pathognomonic for distal hock joint pain, and diagnostic analgesia should always be used to confirm the source of pain causing lameness. Some horses may break from the gait slowly, may not switch leads properly behind, or may crossfire and develop abrasions on the medial aspect of the tarsus (MWC). Horses often wear the lateral aspect of the toe of the shoe. Horses that have a positive Churchill test response likely have distal hock joint pain involving the tarsometatarsal joint (RMA). Some clinicians place emphasis on upper limb flexion, and certainly the response rate is high, but this test lacks specificity. Diagnostic analgesia should be performed to localize pain causing lameness to the distal hock joints. Distal hock joint pain can cause lameness without radiological changes, particularly in young horses, but radiological changes can be present in horses with pain originating elsewhere. Involvement of the centrodistal (distal intertarsal) joint is difficult to assess without radiological and scintigraphic examinations. Nuclear scintigraphy is useful to identify slab fractures of the third and central tarsal bones. Oddly, horses with radiologically evident periarticular osteophyte formation may show little IRU.

The simplest and best treatment is intraarticular injection of methylprednisolone acetate (100 mg) into each affected joint. The centrodistal and tarsometatarsal joints are small, and injecting more than 3 mL of medication without encountering resistance is often difficult. Using hyaluronan gives little advantage, because the joints are low-motion joints (RMA). However, two of us (PJM, MWC) use hyaluronan (20 mg) and methylprednisolone acetate (40 mg), and one of us (MWC) feels strongly that the combination of hyaluronan and corticosteroids prolongs the racing careers of affected horses by delaying progression of OA. Rarely the cunean bursa is injected. There appear to be few complications following repeated injections of corticosteroids into low-motion joints, such as the centrodistal and tarsometatarsal joints. If the diagnosis is correct, the response to therapy is rewarding. However, lameness recurring rapidly after one or two injections may indicate that the primary source of pain is elsewhere or that subchondral pain is a substantial component of lameness. Corrective shoeing may help horses with distal hock joint pain. A high hoof angle (≥ 54 degrees) and the application of slight turndown shoes may help horses push off and may prevent sliding. In horses with primary, chronic distal hock joint pain, turnout or complete rest actually may worsen lameness, and better results are achieved in these horses by maintaining a low level of training (MWC).

The tarsocrural joint usually is not involved, but if effusion exists, one author (RMA) injects the joint with hyaluronan and corticosteroids, because the joint is a high-motion joint. If dark synovial fluid is obtained during arthrocentesis of the tarsocrural joint, cartilage damage should be suspected (MWC). Repeated injections of corticosteroids into the tarsocrural joint should be avoided.

Myositis

Exertional rhabdomyolysis (ER) and nonspecific localized myositis frequently are overlooked sources of lameness in TB racehorses. ER is a common problem, especially in young horses, and primarily is seen in fillies. Male horses can be affected, but much less frequently. Diagnosis usually is not a challenge if a veterinarian observes a hot, sweaty horse with obvious muscle cramps. Lameness is mostly bilateral, is transient after exercise, and resolves within a few hours. A horse with ER should be sound at the trot even when lameness is present at the walk. If ER is suspected and the horse jogs lame, a lameness examination should be performed (JAB). Some horses have unilateral lameness with ER. Colts often develop unilateral forelimb ER, resembling other causes of upper limb pain. Horses may have generalized whole body stiffness if ER is unrecognized and untreated. Elevated serum levels of creatine kinase and aspartate transaminase are necessary to diagnose ER definitively. Horses at risk are given acetylpromazine (5 to 15 mg IV) before exercise to prevent ER. Dantrolene (500 mg PO) given 4 hours before exercise is used in horses that have had serious episodes of ER and have missed training.

Interestingly, some horses are found to have IRU during bone (delayed) phase scintigraphic imaging, and serum muscle enzyme levels may be normal or only mildly elevated. In some horses a history of previous ER is known, but others have no known history of ER. Large muscles or individual muscle bellies within muscles can be affected. Lameness associated with IRU in skeletal muscles may or may not be seen, depending on the muscles involved. These horses typically require rest for a period of 6 weeks (JAB). Muscles of the hindlimb most commonly are affected, such as the gluteal, biceps femoris, and semitendinosus muscles, but forelimb or trunk muscles can be involved, rarely.

Gluteal myositis occurs in TB racehorses. Lameness is characterized by a reluctance to reach forward during the cranial phase of the stride and to push off to extend the hindlimbs at the end of the stride. Lameness may result from a loose, cuppy racetrack that breaks away from the horse. Whether the trochanteric bursa is involved is unclear. Pain is best identified by using direct digital pressure over the greater trochanter of the femur. Local pain is eliminated with injection of corticosteroids (methylprednisolone acetate, 100 mg/site) with an 8-cm, 18-gauge spinal needle into the middle gluteal muscle. The needle is directed horizontally at a 45-degree angle to the sagittal plane toward the opposite tuber coxae. One author (RMA) does not make any effort to inject the trochanteric bursa.

The lumbar region is prone to myositis. Diagnosis is made by palpation of pain and recognition of hindlimb stiffness. An effective treatment is methocarbamol (10 g PO tid). This high dose is effective with no substantial side effects. The withdrawal time for methocarbamol can be long in some racing jurisdictions. Alternatively the affected muscles can be injected with corticosteroids diluted with Sarapin (2.5 mL of a mixture of 50 mL Sarapin and 200 mg methylprednisolone acetate per site).

Other Stress Fractures

TB racehorses are prone to stress-related bone injuries of several sites other than the tibia, including the humerus,

pelvis, and scapula. Humeral stress fractures account for an estimated 5% to 8% of the fatal musculoskeletal injuries in any given year in California. Horses typically develop lameness 45 to 90 days after returning to training, following rest for an unrelated cause. Acute lameness quickly abates within 1 to 2 days, typical of many horses with stress fractures. The cranial phase of the stride is shortened, and the horse may drag the forelimb. This fracture is dangerous. When humeral stress fractures displace, they spiral and invariably cause the destruction of the horse on humane grounds. However, when identified before displacement, fractures heal well without complications. Fractures are nonarticular and rarely recur. Horses are given 90 to 120 days of rest. Scintigraphic examination is the best method to diagnose humeral stress fractures, because location precludes adequate radiographic examination in many horses. Humeral stress fractures occur medially and involve the proximal caudal cortex immediately below the humeral head; the caudal distal cortex (rare); and the cranial, distal medial cortex. Distal-medial humeral stress fractures may be more common in horses training on synthetic surfaces (JAB). Radiographs may show proliferative changes and fracture lines in horses with fractures of the distal, cranio-medial aspect of the humerus, but often in other sites neither the fracture line nor proliferative changes can be seen. Proximally, any loss of distinction in the proximal caudal aspect of the humerus should be considered diagnostic for a humeral stress fracture until proved otherwise.

Stress fractures of the scapula are rare but do occur in the TB, and clinical signs are similar to those caused by humeral stress fractures. Nuclear scintigraphy is the only way to diagnose this fracture. Most scapular fractures occur where the spine of the scapula meets the neck, in the same location as scapular fractures that necessitate destruction on humane grounds.

Pelvic stress fractures are underestimated grossly, overlooked, and misdiagnosed as a source of lameness in racehorses. Pelvic stress fractures most commonly involve the ilium, anywhere from the tuber sacrale to the tuber coxae. Stress fractures at the base of the tuber sacrale frequently are misdiagnosed as strains of the sacroiliac ligament. Fractures involving the base of the tuber coxae can be incomplete or complete (knocked-down hip).

Pelvic stress fractures can be catastrophic injuries, if a fracture becomes complete and displaced and results in laceration of the iliac artery. All horses with stress fractures usually have a history of transient recent lameness. Considerable evidence indicates that catastrophic pelvic fractures develop from preexisting stress-related bone injuries in horses that were continued in training. The incidence is markedly higher in fillies. Nuclear scintigraphy is useful for identifying pelvic stress fractures, but several factors decrease sensitivity, including the overlying muscle mass. Even a minor area of IRU should be considered important. Motion-correction software improves accuracy and image quality. Ultrasonographic examination can be used to identify fracture if displacement exists but is less sensitive than scintigraphy. Ultrasonography is most useful in horses that cannot be moved. Pelvic stress fractures should be included in the differential diagnosis of any TB with hindlimb lameness. Horses returning from training with severe, undiagnosed hindlimb lameness should be tied and not allowed to become recumbent until a pelvic fracture

can be eliminated as a source of pain. Horses with a pelvic stress fracture may not exhibit severe lameness and may be confused with those suspected of having sacroiliac pain or pelvic muscle pain.

Sacroiliac strain is diagnosed in horses when lameness results from slipping while the horse is coming out of the starting gate (MWC). Horses with sacroiliac pain resent pressure applied between the tubera sacrale. Certainly, sacroiliac strain needs to be differentiated from pelvic fracture, because management may include local, deep injections of corticosteroids and Sarapin. Injecting the back or hip muscles in a horse with a pelvic fracture gives no benefit and incurs considerable risk.

The prognosis for horses with pelvic stress fractures is good, unless displacement exists. Even horses with complete, displaced fractures of the tuber coxae can return to racing if the displacement is not severe.

Other Lameness Conditions

Stifle

Stifle lameness causes unilateral and occasionally bilateral lameness in TB racehorses (MWC, PJM). Horses have mild or moderate lameness and appear to swing the limb. Other characteristics include a stiff hindlimb gait, not using the hindlimbs or weak behind, getting out in the straight-away, slipping behind, and locking up behind. The most common clinical finding is effusion of the medial femorotibial joint. Lameness is exacerbated by upper limb flexion. Pain on palpation of the medial collateral ligament is found occasionally.

Diagnostic analgesia is important, but eliminating the lameness totally in most horses is difficult. Radiological findings are generally negative, unless osteochondritis dissecans or subchondral bone cysts are present. Horses with osteochondrosis usually are treated surgically as young horses before arriving at the racetrack. Ultrasonographic examination is useful in identifying soft tissue lesions such as collateral desmitis, and when identified, affected horses are given 7 to 10 days or more of handwalking.

Most horses with stifle lameness appear to have synovitis or early OA. Differences of opinions exist regarding the type of intraarticular injections to use in the stifle. One of us (MWC) uses hyaluronan and betamethasone but avoids using methylprednisolone acetate, because synovitis may worsen. On the other hand, one of us (PJM) uses hyaluronan (50 to 200 mg) and methylprednisolone acetate (160 to 200 mg) in the medial and lateral femorotibial joints.

Secondary Shoulder Region Pain

Horses with forelimb lameness characterized by a shortened cranial phase of the stride may have some degree of secondary muscle soreness in the shoulder region or mild intertubercular (bicipital) bursitis (MWC). Horses often have primary lameness in the foot or fetlock joint, but management of the primary lameness conditions does not alleviate all clinical signs. Injection of a combination of methylprednisolone acetate, isoflupredone acetate, and hyaluronan into the bicipital (intertubercular) bursa and 2 days of handwalking resolves remaining clinical signs in some horses.

The European Thoroughbred

Robert C. Pilsworth

HISTORY OF HORSE RACING IN THE UNITED KINGDOM

As long as people have ridden horses, matches of speed have been held informally between proud owner-riders. Racing horses under saddle was certainly established in England by the time of the Roman occupation. Chester boasts the longest running unbroken series of race meetings in the United Kingdom on the original site, the strangely named Roodeye. This area of land (translated, island of the cross) has been used for horse racing continuously since 1539. Interestingly, racing was introduced to replace football (soccer), which had been banned a few years earlier because of the number of severe injuries and fatalities it produced. The original prize money was substantial for the time, being “in the XXXI yere (31st year) of King Henry Theght (VIII), a bell of sylver, to the value of three shillings and three pence, is ordayned to be the reward of that horse which shall runne before all others.”

Since the time of James I (1603 to 1625), a link has existed between royalty and the town of Newmarket in Suffolk, leading to its reputation as the headquarters of racing in the United Kingdom. Charles I, the successor of James I, established regular spring and autumn race meetings in Newmarket and built a palace and stables, some of which have survived. Racing at that time consisted of matches between pairs of horses, over long distances by modern standards, usually accompanied by hefty personal wagers between their aristocratic owners. Distances as long as 4 to 6 miles were not unusual. During the succeeding two centuries the race distances declined, as did the age at which horses were allowed to race. Initially horses had to be older than 5 years of age, but this was reduced gradually until in 1859 even yearlings were allowed to race. This practice soon ceased, but 2-year-old racing had become established and became, unfortunately in the opinions of many, part of the Thoroughbred (TB) spectrum. During this time the breed itself changed considerably.

Arab horses had been imported sporadically to Britain from the time of the Crusades (twelfth century AD). Usually seized in battle, these Arab horses would have been relatively slow and sturdy horses, used for carrying warriors into battle. In the seventeenth century, a marriage alliance between Charles I and the Portuguese Royal Household allowed Charles access to the Arab horses of the Barbary Coast, and several stallions made the long journey, mainly over land, back to the United Kingdom. Three horses alone—the Byerley Turk, the Darley Arabian, and the Godolphin Barb—founded the entire breed of the TB we know today, producing profound changes in size and

conformation from the native English stock. Eighty percent of the TB racehorses alive today are descended from just one of these stallions, the Darley Arabian, through his great-great-grandson Eclipse.

As the distance of races decreased, speed became an increasing factor, and the fields of competitors increased in size. Eventually the handicap system was introduced in an attempt to avoid the dominance of the sport by a few exceptionally gifted individual horses. All this led to an increase in interest in racing as a spectator sport and a vehicle for gambling. From the nineteenth century onward, racing was more or less recognizable as the sport we enjoy today.

PATTERN OF RACING

The most prestigious races in Europe belong to a worldwide system of accreditation, which groups together races of similar standing. The best horses competing at top level meet each other in a group of internationally acknowledged races known as Group 1. This group includes all the classics in the United Kingdom and the most prestigious races throughout Europe and North America. Beneath Group 1 are two other groupings (Group 2 and Group 3) for horses that have excellent ability but are not up to the extreme rigors of Group 1 racing. Competitors in these races face a weight for performance penalty system. For example, a Group 1 winner running in a Group 2 race carries a weight penalty in an attempt to equalize the competition.

The next tier down from Group races includes the Listed races. Again, the International Pattern Committee decides which races are of sufficient stature to belong to this list. Usually horses enter a Listed race when they have already won a maiden and possibly another race with specific conditions. Such horses have few other realistic options because after two wins a horse carries a lot of weight in an open handicap. Often success in a Listed race increases potential breeding value far more than winning such a handicap. These limited opportunities are often the reason why horses that are good, but not good enough to be top class, are sold out of Europe to continue racing in North America, where races are more suitable. Horses racing in North America are also often able to recoup in prize money the owner's investment, a situation that is often impossible racing in Europe, with its relatively lower prize money.

Beneath the upper echelon of horses racing in Listed and Group company is an open handicap system in which horses are allocated weight according to speed rating. These speed ratings are assessed by professional handicappers, who monitor the performance of the horses when they run in the first three maiden races or less if they win. The horse's rating rises and falls during its racing career, depending on its most recent form. Although this system is obviously open to abuse by trainers running horses at inappropriate distances or on unsuitable ground to lower their racing weight, the system does allow horses of moderate or differing ability to compete against one another on near equal footing and produce an exciting finish. The handicappers' dream is of all horses finishing within a length or so of each other.

Until recently all flat racing in the United Kingdom took place on turf. This led to a certain divergence in bloodlines and ability patterns of racehorses in North America and Europe. About 20 years ago, all-weather racing on a synthetic surface was developed at two tracks, Lingfield and Southwell. Although initially introduced for hurdle racing as a way of keeping the betting public satisfied when the National Hunt cards had to be abandoned through bad weather, both tracks rapidly discontinued hurdle racing on all-weather surfaces because of the high injury rate. This left the way open for flat racing on the all-weather tracks to become established. Since that time, new synthetic tracks have also opened at Wolverhampton, Kempton, and Great Leighs.

The synthetic all-weather track surface is not the same as the dirt commonly used in North America. The depth of the cushion is greater, and the material is a composite of oil, plastics, fibers, and sand. Few races with large prize money are run on the synthetic surfaces, and the racing has tended to be of a more humble grade, but that is slowly beginning to change. These tracks give horses of limited ability somewhere to race and also allow trainers with small stables to compete with each other in the absence of both top-level horses and the larger yards, although this too is beginning to change. Several successful all-weather horses have made a transition to racing in North America to end up running in Group (graded stakes) races on dirt, and the all-weather surface can act to some extent as a screening academy to pick out horses that seem particularly adept at performing on these artificial surfaces, although not all horses make a successful transition from synthetic surfaces to dirt racing.

Flat racing is popular in the United Kingdom, Ireland, and France but less so in the rest of Europe. Although training centers exist in Germany along with a substantial number of high-grade races, flat racing has not really caught the imagination of the public in the same way as in Britain and Ireland and receives little media attention. Ireland always has had a strong tradition of horsemanship, and racing, centered around the Curragh, is buoyant and popular. Standardbred racing is equally popular in France, Germany, and Scandinavia, where flat racing opportunities are limited. Many European countries enjoy racing in the absence of a substantial breeding industry, and this creates a market for the surplus racehorses produced and raced in the United Kingdom, Ireland, and France. Horses in these countries are raced at 2 years of age and, ability permitting, 3 years of age, and at the end of the 3-year-old career many are submitted for sale if they have not shown sufficient ability to be retained for racing as older horses. This makes room in the yards for the incoming yearlings. These large dispersal sales at the end of the 3-year-old career supply the horses for National Hunt racing in the United Kingdom and for flat racing areas of the world lacking breeding programs. The need for yards to clear out the less gifted 3-year-olds to make room for the influx of yearlings also produces enormous pressure on trainers and consequently their veterinary surgeons to have a racehorse fit and able to race at 2 and 3 years of age, often without consideration for the long-term consequences of any treatments.

The small window of opportunity available to these horses impinges directly on many of the surgical and medical management decisions that need to be made when

problems arise. The economics and practicality of any advice given have to be considered from the owner's viewpoint and the welfare of the horse.

COMPARISONS WITH RACING IN NORTH AMERICA

One of the major differences between training and racing in North America and Europe is in the geographical location and logistics of stabling and training of the horses. In the United States, almost all horses train at the racetrack and are stabled there continuously. In Europe, the horses live and train in yards often well away from the racetrack. These yards tend to be clustered around a training area, with gallops and conditioning canters available for use by local trainers. The horses travel daily to race at racecourses that may be up to 200 miles away.

In the United States, the horses, trainers, jockeys, and veterinary surgeons tend to move from one racecourse to another, but they stay at each track for long periods. Racing at each location takes place for many days or even weeks before horses and trainers move on to another track. Although some horses stay behind at one track, racing does not occur at that track when the primary focus is elsewhere.

In Europe, racing seldom occurs at any one racecourse for more than 3 consecutive days. Horses are trained in traditional stables, some of which date back many centuries. Horses travel to racecourses the day before racing, if the journey is particularly long, or even on the day of the race. Some horses make extremely long round trips. For example, it is not unusual for a trainer in Arundel on the south coast to send horses as far north as Ayr in Scotland, a round trip of 936 miles. Obviously the cost of transport has to be weighed against the potential gains, but the traditional system of training and traveling to the races in the United Kingdom seems to be holding up for now.

In 2000, two of the all-weather racetracks opened training barns adjacent to the track with a view to introducing American-style training, track side. How popular and successful this system is going to be and whether it will spread to other racecourses remain to be seen.

In North America, almost all training and racing takes place on a left circle (counterclockwise), and this might be expected to have influences on the incidence rates of injury to the left and right limbs for many lesions, such as proximal sesamoid bone (PSB) fractures, third metacarpal (McIII)/metatarsal (MtIII) bone condylar fractures, and tendonitis (see Chapter 106). In the United Kingdom, much conditioning work and even race speed training take place in straight lines ([Figure 107-1](#)). Racing itself can be on straight tracks (e.g., 1000 and 2000 Guineas at Newmarket), predominantly to the left (Epsom Derby), or to the right (Doncaster St. Ledger). The tracks themselves divide into about one third right-handed and two thirds left-handed throughout the country. This has an important impact on the lack of specific incidence of injury to the left or right limbs. One large fracture survey in Newmarket showed few instances of left or right dominance for any injury.¹

Making categorical comments about the impact the new synthetic tracks have made on specific lameness and injury in the United Kingdom is difficult for several reasons:

Fig. 107-1 • A, Horses approach the finish of the long and lonely Rowley mile racetrack at Newmarket. This photograph illustrates the undulating nature of the straight 1-mile track over which both 3-year-old Group 1 classics are run. **B,** The long straight of the training track gallops up Warren Hill just outside Newmarket. Two different all-weather synthetic surfaces are also available (between the white railings). The rest of the heath is used in strips, which are changed daily using movable markers. Each strip of grass is used only once every 3 years.

1. Although the racing is on a specific surface, because of the way British horses travel long distances to race, the horses in any race have trained on a variety of surfaces at home. Because it is believed that the accumulation of the daily work sets up stress-related injuries, the actual failure that may take place in a race often can have little to do with the track surface on which the horses are racing that day.
2. Tendonitis is relatively rare in the populations of 2- and 3-year-olds in a large flat training yard, and one might expect to see one bowed tendon in a yard of 100 horses in any one season. Horses that race on all-weather tracks have a far higher incidence, but they often include many older horses (3 to 9 years of age) and a higher number of horses with chronic, low-grade gait abnormalities, both of which could help to increase the incidence of tendon injuries.
3. The incidence of fractures in horses racing on all-weather surfaces seems to be higher than on good grass, but turf described as firm or hard is just as testing. Generalizations about turf versus artificial surfaces in terms of impact on injury have to be more specific because turf

can vary from bottomless mud to baked clay in midsummer. The older population of horses that race on the all-weather tracks, many of which carry a legacy of subchondral bone change from the previous training at 2 and 3 years of age for turf racing, could influence the higher incidence of fractures.

TRAINING REGIMENS IN EUROPE

Yearlings arrive in the yards for breaking from the sales in September and October and, unlike the situation in North America, often go straight to the trainer for breaking rather than to a specialist pretraining center.

After breaking, the yearlings usually start steady cantering exercise until Christmas. As the racing season approaches, horses showing precocity and ability to withstand faster exercise step up in pace throughout February and March. The first 2-year-old races occur in April, encouraging hard training of skeletally immature horses. However, until the racing calendar changes and while these races are open and available, trainers will train horses for them.

All-weather racing has altered the seasonal impact of flat racing in the United Kingdom forever, and some flat race horses now train throughout the year. However, most of the high-quality flat race horses do not compete on the all-weather circuit and are put into a slow-speed maintenance program from November until January, involving light cantering and trotting. Fillies may be turned out for a period.

All this is substantially different from the position in North America, where the horses often do not arrive at the racetrack until they are fully broken, in cantering exercise, and ready to do fast work. The breaking and pretraining often takes place in specialized pretraining centers, away from the city center tracks. This has important effects on the perception of racetrack veterinarians in North America concerning the incidence of developmental orthopedic disease linked to lameness. In North America, developmental orthopedic disease often causes lameness leading to diagnosis and removal from training *before* a horse reaches the racetrack; therefore horses with developmental orthopedic disease are not commonly seen by track veterinarians. An example is a subchondral bone cyst in the medial femoral condyle. Subchondral bone cysts are a regular occurrence in the annual intake of yearlings in the United Kingdom, diagnosed by the trainers' veterinarians. Discussion with colleagues working at California racetracks reveals that they rarely see horses with subchondral bone cysts, presumably because of the effect of the earlier screening at the pretraining centers.

Once on the track in North America the racing is often less seasonal and less age specific, removing a lot of the pressure for success at 2 or 3 years of age within a short season. Whether a horse races on turf or dirt does not matter: historically, all training took place on dirt, and this should be borne in mind by veterinarians assessing horses for potential purchase to move from Europe to America. Asking potential purchasers whether the horse is intended for turf or dirt racing is largely irrelevant because the daily training almost certainly will be on dirt. The dirt surface is more testing in many ways than anything these horses have seen before, and horses able to train and perform well on grass sometimes fail to make the transition to dirt. In

the past couple years, a few training tracks and racetracks in North America have moved to synthetic surfaces. It will be interesting to see whether this makes for an easier transition for horses moving from Europe to race in North America, and what impact it has on the types and frequency of training and racing injuries.

CLINICAL HISTORY

Taking a detailed history is a prerequisite for a medical examination in any species. In racehorse practice one often sees a succession of lame horses during any morning in several different yards, and the detailed information may be limited. The trainer may not be present to supply it. However, one should always try to ascertain the following information before examining a TB racehorse for lameness:

1. How old is the horse? This is probably the single biggest determinant for different types of lameness. The chronological age is important, but far more important is the skeletal naivete of the horse. An unbroken horse of 3 or 4 years of age behaves in essentially the same way as an unbroken yearling, regardless of the difference in age, and may suffer similar problems when confronted with an inappropriate training program.
2. What stage of training has the horse reached? Has a horse reached race-speed exercise yet; is it simply trotting; or has it entered normal conditioning cantering exercise? For a yearling that is lame while being broken or in early cantering exercise, one has to consider subchondral bone cysts and other osseous cystlike lesions, osteochondritis dissecans (OCD), and associated osteoarthritis (OA). Problems may be bilateral, resulting in a peculiar gait. Bilateral ilial wing stress-related bone injury or sacroiliac joint pain considerably affects the freedom of movement of the hindlimbs and may mimic the clinical signs of exertional rhabdomyolysis, but plasma creatinine kinase (CK) levels often will be normal or only slightly raised (500 to 1500 IU/L).
- Stress-induced bone injuries are more likely to become apparent as work intensity increases. Stress-induced bone injuries include all of the long bone stress fractures of the humerus, tibia, the McIII, and the MtIII, and the ilial wing and shaft of the pelvis. Similarly, in a 2-year-old that has reached advanced training speed, the carpus and metacarpophalangeal joint are common sources of forelimb lameness, and lateral condylar stress injuries of the MtIII are common causes of hindlimb lameness. A 2-year-old in advanced training is less likely to have lameness associated with a subchondral bone cyst, osseous cystlike lesion, or OCD because these lesions usually cause lameness when the horse is younger and beginning its conditioning exercise. However, occasionally subchondral bone cysts and osseous cystlike lesions may arise or result in clinical signs for the first time at 3 years of age or even older.
3. Has the horse raced yet? If a horse has raced successfully at 2 years of age, the horse is unlikely to have hidden osseous cystlike lesions or OCD. Also, the skeleton has probably been conditioned adequately, and the incidence of stress fractures can be expected to be lower. However, in countries where racing is seasonal, 3-year-olds can "detrain" through the closed season if they are

not maintained in cantering exercise. Stress fractures then may occur in the following season if speed training starts too quickly. A Californian study showed an associative link between the occurrence of stress fracture of the humerus and previous long-term removal from training.²

If a horse did not race at 2 years of age, then all the differential diagnostic criteria used in the recently broken 2-year-old should be applied to the 3-year-old.

4. Has the horse had any previous orthopedic problems? Often in practice one knows each horse individually, and one is able to recall the problems that affected the horse in its early years. The history of a horse with previous problems may guide the use of diagnostic analgesia in an unorthodox, but timesaving, manner to establish whether the current lameness is a recurrence of a previous problem.
5. What is the pattern of the lameness? One should ascertain whether the lameness is constant from day to day and for how many days the horse has shown a gait abnormality. The veterinarian should ask whether the lameness gets better or worse within an exercise period. In some conditions, such as proximal suspensory desmitis (PSD), the lameness tends to get worse as the horse exercises, only to resolve with 24 to 48 hours of rest. Horses with lameness from other causes, such as OA, often warm out of clinical signs considerably from the start of exercise.

In horses with acute-onset, severe lameness, questions of clinical history become less important because the horse is often not bearing weight, and a suspicion of skeletal failure is raised. Knowing whether this horse has been a good mover before onset of severe lameness is often helpful because some injuries (McIII/MtIII bone condylar fractures, PSB fractures) often are associated with poor gait before the actual fracture takes place. The same is true of horses with slab fractures of the third carpal bone, which often are preceded by a long period of subchondral bone sclerosis associated with bilateral third carpal bone pain (Figure 107-2). One of the most useful questions to ask about a horse with severe lameness is what stage of training the horse has reached because only advanced training to fast canter or gallop speeds usually results in bone failure. However, bacterial infection subcutaneously or within the hoof also can produce severe lameness.

6. Has the horse had a prolonged layoff for any reason? Horses brought back from a long period of box rest after illness or injury, without adequate previous bone conditioning, can get bizarre injuries from unusually low-speed exercise. These include complete, displaced scapular and humeral fractures, bilateral fractures of the PSBs and tibias, or displaced fractures of the proximal phalanx or condyles of the McIII. This is a reminder of the vital need for time to allow adequate skeletal conditioning necessary to avoid injury.

Clinical Examination

The veterinarian always should get the horse out and see it walk and trot to determine which limb is lame. Riders are notoriously unreliable at detecting the correct lame limb. The veterinarian should determine whether the lameness is unilateral or bilateral by the way the horse

Fig. 107-2 • Flexed dorsal 60° proximal-dorsodistal oblique radiographic images of the left third carpal bone (C3) of three Thoroughbreds (TBs). Lateral is to the right. **A**, Normal. However, this complete lack of increased radiopacity is rare in a TB in advanced training, most of which show some degree of radiopacity of the radial fossa of C3. **B**, Dense increased radiopacity of the radial fossa of C3. Normal trabecular pattern is lost, and the bone has a “ground glass” appearance. There is increased osteolysis at the site of a normal nutrient foramen (arrow in the center of increased radiopacity). This stiffening of the bone predisposes it to injury or fracture. **C**, A nondisplaced sagittal fracture of C3 that propagates through the center of an area of severe increased radiopacity representing mineralization of bone (arrows).

moves. Many racehorses are slightly lame in all limbs and have a typical crouching, shuffling trot or may try repeatedly to break into a canter because trotting is so uncomfortable. New lameness may be superimposed on a chronic level of unsoundness.

Increasing experience usually leads one away from the belief that any one injury is linked to a particular gait. Lameness typical of a shoulder or a stifle tends to become a more remote belief because so-called typical lamenesses so often are linked eventually to the most unexpected site. However, a few types of lameness do remain that seem to

be linked to one particular pathological syndrome. Young TBs often show bilateral forelimb lameness related to carpal pain. These horses often trot with the limbs abducted from the midline and not fully flexed during forward motion. This gives a rolling, stiff-legged forelimb gait. The horse’s attempt to get the contralateral limb down quickly to get off the sore limb as soon as possible shortens the forward phase of the stride, leading to a choppy, stilted action. However, horses affected with bilateral front fetlock pain or PSD trot in a very similar way if the pain level is the same in both limbs, and it may simply be that because carpal lameness is a common manifestation of this gait, we have come to link the two more firmly than we should.

Pain associated with the metatarsophalangeal joint is often bilateral and leads to a fairly characteristic gait typified by low limb flight, often with dragging of the toe during protraction, and an exaggerated rocking pelvic excursion dorsoventrally on both sides (sometimes termed the *Marilyn Monroe trot*) because the horse dips off each painful limb. Horses with a humeral stress fracture often abduct the limb, with shortened cranial protraction at the walk. One Newmarket trainer described this gait recently as “trotting like a pig in a tight skirt,” which, although not a likely scenario, is in fact just how they look..

Having ascertained which limb is the lamest, the limb should be examined in detail using basic examination protocols (see Chapters 4 through 8 and 10). The following specific points apply to the TB racehorse.

1. Many racehorses show a pain response to squeezing of the foot with hoof testers, which is not related to a current lameness. The TB has a thin-soled foot, which often is shod incorrectly, causing soft-tissue bruising on the palmar aspect of the foot. If the horse responds to hoof testers in the lame limb, I normally test the contralateral foot to see whether the response is different. If the response to hoof testers is the same in both limbs, the foot may not be the primary source of pain causing lameness.
2. Suspensory branches are best appraised by centering each branch between opposing thumbs and following the branch from the most proximal portion that is palpable distally to the PSB. Subtle thickening in the suspensory branch not palpable with fingertips may be detected as the thumbs separate running toward the PSB.
3. The metacarpophalangeal joint should be checked for distention of the palmar pouch of the joint capsule. Thumb pressure is applied to the dorsoproximal aspect of the proximal phalanx and the dorsodistal aspect of the McIII, common sites for fragmentation and impingement lesions producing soreness. The limb then should be flexed partially and the response to flexion of the metacarpophalangeal joint monitored. Many young horses show a mild pain response to flexion, and the contralateral limb should be compared to gauge whether a difference exists. However, in a 2-year-old a bilateral pain response may reflect true problems in both limbs. In a normal horse the metacarpophalangeal joint should not be painful to flex.
4. The proximal aspect of the suspensory ligament (SL) should be examined with the limb raised by squeezing the ligament between the thumb or fingertips and the palmar surface of the McIII, first medially and then laterally. Normal untrained horses show no pain

response. However, many young racehorses show a variable degree of discomfort on SL palpation. Differentiating pathological and normal response to palpation associated with increased training can be difficult.

5. The dorsal surface of the McIII should be squeezed using the fingertips with the limb raised and the pain response noted as an indication of sore shins. The surface of the shin should be palpated for periosteal thickening or even focal callus formation associated with a stress fracture.

Running a finger distally on the shin with a horse bearing weight often causes a horse to buckle the limb even if it has been months or even years after shin soreness has subsided and is not a reliable diagnostic test.

6. To detect distention of the antebrachiocondylar or middle carpal joint capsules, pushing on the dorsal surface of the joint with the finger and thumb of one hand while observing the palmar pouches of the joints is useful. Mild effusion then may be detected.
7. Many young racehorses resent extension of the shoulder joint in the absence of a lesion.
8. Many racehorses mildly object to forced tarsal flexion equally in both hindlimbs unrelated to a lesion. A profound response to flexion of the tarsus of the lame limb, which is not matched in the contralateral limb, usually signifies a tarsal bone fracture or a stress fracture of the distal aspect of the tibia. If pain is noted on flexion, thumb pressure should be applied to the proximodorsal aspect of the MtIII and the dorsolateral surface of the tarsal bones to determine a pain response. Pain response is often marked if there is a slab fracture of the third tarsal bone.
9. The tibia is a common site for stress fractures and is examined by curling the fingers around the caudal surface of the tibia from the medial aspect and squeezing on a common predilection site for stress fracture, the caudal surface of the distal third of the tibia. Torsion of the tibia also is attempted by flexing the limb, applying lateral traction to the os calcis with one hand while maintaining firm contact on the stifle with one's shoulder, and medially twisting the distal aspect of the MtIII with the other hand (Figure 107-3). A horse with an incomplete linear stress fracture will show a profound pain response to torsion and may try to kick. It may also not want to take weight on the limb for a few seconds after its release, which is a sign characteristic of marked cortical involvement. The other limb should be examined, bearing in mind that these fractures can be bilateral, although pain and degree of lameness are often asymmetrical.
10. The pelvis is another frequent site of stress fractures and is examined by monitoring the position of the bony landmarks—the tubera sacrale, tubera coxae, third trochanter of the femurs, and tubera ischia—looking for displacement (see Chapter 49). Response to deep palpation of the muscles that lie between these sites is also noted. The most common clinical sign in horses with a nondisplaced pelvic fracture is guarding of the musculature as a response to deep palpation. Guarding gives a hard, boardlike texture to the muscle and often is accompanied by fasciculation of the gluteal mass and an avoidance response. Similar clinical signs can be seen in horses suffering from exertional

Fig. 107-3 • Application of torsion to the tibia. The metatarsophalangeal joint is rotated medially, the os calcis laterally, and firm shoulder pressure maintained with the stifle. Horses with a stress fracture of the tibia often show a sharp pain response to this test and will often be unwilling to bear weight on the limb for some seconds subsequently.

rhabdomyolysis, and this may be a difficult differential diagnosis to establish. Muscle enzyme concentrations may be elevated (CK, 500 to 1500 IU/L) in horses with a pelvic fracture. The tail should be raised and lowered, and tail tone should be monitored. A flaccid tail often indicates a sacral or coccygeal fracture.

Imaging Considerations

Radiography and Radiology

Many lesions in the TB racehorse are associated with subtle changes in bone density and structure rather than overt fragmentation of bone. These variations result in subtle changes in radiopacity (increased radiolucency or radiopacity), which often are seen best on high-quality radiographs using single-screen film and excellent radiographic technique or more recently by using digital radiography. However, we should be aware when using digital radiography that the “standard” appearance of bone is lost. By altering the algorithms and scaling, we can alter contrast and obliterate the signs of increased radiopacity of bone at will. This is particularly true in appraisal of the “skyline” projection of the third carpal bone, where assessment of increased radiopacity is critical in advising on future workload of young horses and can be made MORE difficult by the ease of image manipulation now available to us digitally.

Radiography is notoriously unreliable in detecting early fracture lines and subchondral bone collapse. For this reason, if lameness is linked to a particular site by diagnostic analgesia and nothing is visible radiologically, repeating the radiography 2 weeks later is often advisable. Any horse with subtle changes in bone density can be rested long

Fig. 107-4 • A, Weight-bearing dorsal 20° proximal-palmarodistal oblique radiographic image of a right metacarpophalangeal (MCP) joint. Lateral is to the left. No gross abnormality is seen. **B**, Flexed dorsal 125° distal-palmaroproximal oblique radiographic image of the same MCP joint. There is an incomplete linear fracture (arrow) in the lateral condyle that was not visible on any other image.

enough where additional damage can be seen. During investigation of individual joints, special projections are often most useful (Figure 107-4). Radiographic examination of the metacarpophalangeal and metatarsophalangeal joints always should include the flexed dorsopalmar image, which is extremely useful for evaluating the palmar and plantar aspect of the condyles (see Figures 107-4 and 107-5).^{3,4} In a hindlimb this view often is achieved best as a plantarodorsal image. The limb is cupped loosely by a hand underneath the tarsus and allowed to hang in a semiflexed position. The cassette is placed in a cassette holder and positioned on the dorsal aspect of the metatarsophalangeal joint, and the x-ray machine is positioned above and behind to achieve the orthodox 125-degrees image.

The lateral condyle of the MtIII bone is a predilection site for subchondral bone injury, represented by sclerosis in the early stages and subchondral bone loss and radiolucency as the condition advances. This can be highlighted by a dorsal 30° proximal 45° lateral-plantarodistal medial oblique image (down angled oblique) developed by Ross⁵ (see Figure 107-5, C).

Another unorthodox image that can be helpful in trying to evaluate subchondral bone radiopacity and fissuring in the distal palmar/plantar aspect of the McIII/MtIII is a steeply angled (60°) dorsopalmar/plantar image (i.e., dorsal 60° proximal-palmarodistal oblique view), centered on the palmar/plantar aspect of the condyles, projecting the PSBs proximally. Areas of fissuring and radiolucency adjacent to the sagittal ridge of the McIII/MtIII or prominent increased radiopacity of the subchondral bone can sometimes only be seen on this image (see Figure 107-5, A). This image was developed in response to frustration in being unable to see marked changes in this site seen on magnetic resonance imaging (MRI) examination using conventional radiographic images (Figure 107-6).

Radiographic examination of the carpus always should include a flexed dorsal 55° proximal-dorsodistal oblique (skyline) image of the third carpal bone, which is sometimes the only image in which lesions in this bone can be seen clearly. The image is easy to do well but is still often done poorly. Small changes in the angle of projection make a substantial difference to the amount of the third carpal bone visible in the resultant image.⁶ One should not be satisfied unless the entire radial fossa is seen clearly (see Figure 107-2).

The relevance of changes in bone density should not be underestimated. Many stress fractures of the long bones are seen only by the occurrence of endosteal or periosteal callus. Periosteal callus may only be visible with the aid of a bright light or more extreme digitally produced “windowing.” Fracture lines are relatively rare. Despite the difficulty in imaging incomplete fracture lines sometimes, some horses may go on to develop complete, displaced fractures during periods of box rest, reminding us that the evidence must have been there if only we could have seen it.

Scintigraphy

Scintigraphy has allowed enormous advances to be made in the detection and understanding of stress fractures in the racehorse.⁷⁻⁹ Scintigraphy should not be used as a first line of investigation in horses with obvious single-limb lameness, unless a strong clinical suspicion exists that the humerus, pelvis, or tibia is involved and radiography has been unrewarding. Examination of an entire TB racehorse that cannot trot and has multilimb lameness is often useful. These horses are difficult to assess using diagnostic analgesia because one is often racing against time, moving from one limb to another with the predominant lameness constantly changing. Scintigraphy in these horses often results in a list of lesions that can be investigated

Fig. 107-5 • **A**, Dorsal 60° proximal-palmarodistal oblique image of the left metacarpophalangeal (MCP) joint; lateral is to the right. This steeply angled dorsopalmar image was developed in an attempt to see subchondral bone change diagnosed by magnetic resonance imaging examination, but not seen on conventional radiographs. There is a zone of severe bone mineralization (increased radiopacity, arrows) associated with an advanced subchondral bone injury in the medial condyle. Normal trabecular pattern of the condyle is lost (cf., lateral condyle). **B**, Dorsal 60° proximal-palmarodistal oblique image of a right fore MCP joint; lateral is to the left. There is less marked mineralization of the medial condyle (white arrows) than in **A**, but there is radiolucency/fissuring in the most palmar portion of the parasagittal aspect of the medial condyle (black arrows). This horse was lame at the walk, and pain was localized to the MCP joint by local analgesia. This fissuring was not visible on orthodox radiographic images. **C**, Dorsal 30° proximal 45° lateral-plantarodistal medial oblique image. This image highlights the region of the lateral condyle in contact with the lateral proximal sesamoid bone when the joint is at full weight bearing, a common site of focal stress injury. Focal bone mineralization (increased radiopacity) is evident (white arrows) with a central area of radiolucency (black arrow), which probably represents bone necrosis and resorption. This degree of change is usually irreversible and associated with chronic lameness. These changes cannot be seen on any other radiographic image.

radiologically and by judicious use of diagnostic analgesia. The other roles of scintigraphy include examining a site identified by diagnostic analgesia but in which no abnormality can be found radiologically and safety screening of an initially severely lame horse that has become sound before a diagnosis has been reached. Thus making a diagnosis in these horses at post mortem is avoided. Clients should be educated to not request the scintigraphic “fishing trip” as a first line of enquiry.

Ultrasonography

Ultrasonography is the imaging modality of choice for investigating soft tissue injuries in the metacarpal and metatarsal regions (see Chapter 16). In the young TB affected with PSD, lesions are often subtle, with enlargement and bulging of the palmar border with consequent loss of the neat rectangular shape of the normal SL as the only finding.¹ Large anechogenic defects and obvious fiber tearing are not common.

The clinical relevance of bilateral enlargement of the superficial digital flexor tendons along with intratendinous edema in a 2-year-old may be difficult to interpret because normal tendons increase in size in response to training¹⁰ (see Figure 99-2). If obvious distortion of the contour of the tendons exists, I advise that the horse not gallop or race at 2 years of age. The horse is maintained in alternate-day trotting and cantering for 3 months. This treatment

has not led to true tendonitis at 3 years of age in any horse. I refer to these horses as having juvenile tendonitis but have never been comfortable that this degree of caution is mandatory. Perhaps these horses could do more work without further injury.

Ultrasonography is also useful for detecting and monitoring some fractures of the ilial wing and shaft and ischium of the pelvis (see Chapter 49).

Diagnostic Analgesia

Having carried out the clinical examination described, one structure causing lameness may be obvious. For example, the horse may show a sharp pain response on palpation of the SL or distention of the middle carpal joint capsules with pain on flexion. Diagnostic analgesia may not be necessary in these horses, and diagnostic imaging of the site may be the next step. Many horses have a list of diagnostic possibilities: the horse may have shown a pain response to hoof testers and some tenderness to palpation of the SL and have some distention of the middle carpal joint capsule. To tease apart these findings, diagnostic analgesia is mandatory. Diagnostic analgesia is done most efficiently at a clinic rather than a training yard because the procedure is time consuming. If a horse is fresh when admitted for diagnostic analgesia, the increase in muscle tone and general excitement can obscure a mild lameness, and acetylpromazine (2 to 5 mg/horse

Fig. 107-6 • Dorsal 15° proximal-palmarodistal oblique (A) and lateromedial (B) images of the left fore fetlock of a 2-year-old TB, with lameness localized to the metacarpophalangeal (MCP) joint by regional and intraarticular analgesia. There is mild increased radiopacity of the palmar aspect of the medial condyle (arrows), but within the range one might encounter in sound horses. T1-weighted gradient echo motion-corrected low-field magnetic resonance images, dorsal (C) and parasagittal (D) plane, of the same MCP joint. There is diffuse marked decreased signal intensity within the palmar aspect of the medial condyle (arrows) and to a lesser extent in the lateral condyle. This is consistent with mineralization (bone sclerosis) underestimated in the radiograph. (Courtesy Sarah Powell, Rosedale and Partners, Newmarket, England.)

intravenously) can help settle the horse without affecting its ability to trot.

If the horse is admitted to a clinic for a day, a positive block can be allowed to wear off, so that more localized blocks can be carried out. For this reason, my own first block in a forelimb is usually biaxial palmar digital nerve blocks so that the foot can be eliminated or investigated in greater detail later. Many horses with mild lameness exhibit a detectable worsening of the degree of lameness if the foot is desensitized and is not the source

of pain, which can be useful when investigating intermittent or low-grade lameness. I used to first perform palmar (abaxial sesamoid) blocks, but I increasingly found that this often abolished pain from the fetlock or the distal metacarpal or metatarsal regions and thus was not reliable as an indicator of primary foot pain.

If lameness is abolished using palmar digital analgesia, a more detailed investigation of the foot and distal extremity is carried out, perhaps with the shoe removed. If effusion of the distal interphalangeal joint is present, an

intraarticular block is performed. In rare instances, palmar digital nerve blocks will abolish pain later proven to originate from the distal condyle of the McIII or the MtIII; therefore this should also be checked by intraarticular analgesia of the fetlock joint if the subsequent block results do not make logical sense.

If the horse is unchanged after palmar digital analgesia, a low palmar and palmar metacarpal (four-point) block is used. This may alleviate lameness; not improve lameness, indicating the problem is much higher; or give a 30% to 50% improvement in lameness, which is observed commonly in horses with PSD. However, recently I have become aware that horses with severe, advanced subchondral bone sclerosis and injury of the distal aspect of the McIII/MtIII seen on MRI may not be rendered completely sound by either a low four-point block or intraarticular analgesia of the fetlock joint, although the lameness may be substantially improved by both. There is a danger if one assumes that a 50% improvement in lameness following a low four-point block, followed by total soundness after a subcarpal block indicates that the origin of pain is in the proximal aspect of the SL or the McIII. This block response may divert attention away from the actual site of pathology in the fetlock.

The next logical step is the subcarpal block, which I perform using 1.6-cm needles and 2.5 mL of mepivacaine in the recess immediately palmar to the top of the second and fourth metacarpal bones. Short needles and small volumes of local anesthetic solution are used in an attempt to reduce the frequency of false-positive analgesia of the middle carpal joint. False-positive responses can occur by inadvertent direct penetration of the distopalmar outpouchings of the carpometacarpal joint^{11,12} or by diffusion of local anesthetic solution up the fascial planes to a site proximal to the middle carpal joint.

A positive subcarpal block is always allowed to wear off, and the middle carpal joint is blocked subsequently to ascertain which site is responsible for the pain causing lameness. Unfortunately, in some horses complete soundness follows both the middle carpal joint and subcarpal blocks. When this occurs, ultrasonographic examination of the proximal aspect of the SL and a radiographic examination of the carpus are performed before an informed guess is made about the most likely source of lameness. If no lesions are found after imaging both sites, defining the source of pain categorically may not be possible, and the horse is a candidate for nuclear scintigraphy. MRI is also proving extremely useful in unpicking the complexity of lameness in this site.¹³ I avoid using the lateral palmar nerve block because in my hands it is too nonspecific and has abolished lameness that originates from the SL, proximal aspect of the McIII, and both joints of the carpus on occasions. In an experimental study, no penetration of the antebrachiocarpal and middle carpal joints occurred as a result of lateral palmar analgesia, although commonly the carpal synovial sheath was penetrated (Editors).¹²

Negative subcarpal and middle carpal analgesia are followed by median and ulnar nerve blocks. Although these blocks leap-frog the antebrachiocarpal joint, median and ulnar nerve blocks usually abolish lameness associated with lesions of this joint. Intraarticular analgesia of the antebrachiocarpal joint may fail to abolish pain associated with chip fractures of the distal aspect of the radius in some

horses.¹⁴ The jump directly to median and ulnar blocks avoids the possibility of false-negative responses misleading the lameness diagnosis.

Negative median and ulnar blocks usually are followed by advice to carry out scintigraphy because scapulohumeral joint lameness is relatively rare and intraarticular analgesia does not alleviate lameness associated with humeral stress fractures, which are common. Although OCD and osseous cystlike lesions of the scapulohumeral joint are found in late yearlings and early 2-year-olds, these often show scintigraphically and can be confirmed later by radiological examination and diagnostic analgesia if necessary. Intraarticular analgesia of the elbow and scapulohumeral joints is performed if the median and ulnar blocks and scintigraphy fail to establish the seat of pain causing lameness. However, it has been my experience that intraarticular analgesia of the elbow joint can on occasion abolish lameness later proven to have originated from a site more distal in the limb, presumably by diffusion of local anesthetic solution from the joint in proximity to the median nerve; therefore a positive elbow block may need to be interpreted with caution.

Hindlimb investigation follows a slightly less rigorous approach for three reasons:

1. Some young TBs become difficult with repeated needle entry of the hindlimbs, resulting in a serious risk to the veterinary surgeon, the member of staff holding the horse, and the horse itself.
2. The common occurrence of stress fractures in the more proximal sites in the hindlimb, particularly in the tibia and the pelvis, means that many horses potentially would be blocked in detail from toe to stifle, without producing any improvement in lameness. For this reason a six-point (low plantar) block above the metatarsophalangeal joint is performed first in a hindlimb. A positive response to a six-point block is allowed to wear off, and the response to intraarticular analgesia of the fetlock joint is assessed. If these blocks produce negative results, a subtarsal block is performed, followed by tarsometatarsal (TMT) joint analgesia. If the horse behaves satisfactorily, tibial and fibular (peroneal) nerve blocks are performed. It is common for pain originating from stress fractures of the distal aspect of the tibia to be abolished by tibial and fibular nerve blocks, and postblock radiographic screening after a positive result to this block should include the distal aspect of the tibia. If lameness is still present, the horse may be allowed to rest, undiagnosed, or the stifle is examined radiographically, or scintigraphy is performed, depending on the wishes of the trainer and owner. Only if lameness recurs after a period of rest and the absence of a scintigraphic diagnosis are the stifle joints blocked.
3. Bilateral lameness associated with subchondral injury to the lateral condyle of the MtIII is common in TBs and often can be abolished by blocking the lateral plantar metatarsal nerve only, just dorsal to the button of the splint, using 2 mL of local anesthetic solution.¹⁵ This often produces an overt lameness in the contralateral limb. This block is easy to perform, and the problem is common; therefore it is tempting to use this block first in horses showing the typical bilateral tight, choppy gait abnormality often seen in this condition.

Shoeing Considerations

TB racehorses have notoriously bad horn quality and hoof conformation. They appear to have uniformly thin soles and a tendency to develop long toes and low heels. Medial to lateral hoof balance is vital to the TB racehorse remaining sound, but it is sometimes not pursued adequately. All horses should be shod wide at the heel to allow full weight bearing by the horn structures. However, in racehorses this tends to produce an abundance of pulled shoes by the trapping of the metal of one shoe underneath the other foot in the stable, particularly on rubber floors, which do not allow the trapped shoe to slip out. This encourages farriers to tuck the shoes out of reach under the foot, which leads to progressive collapse of the heel and long-toe, low-heel conformation. Farriers have to be reassured that they will not be held responsible for pulled shoes within the stable and that the health of the horse's foot is more important than the management problems sometimes associated with correct shoeing.

Interference injuries are not as common in the TB as in Standardbreds and are more common when horses are on a reduced exercise plane or in 2-year-olds in early training. Interference injuries seem to become less common as the horse strengthens and becomes more fit. In every horse such injuries should be approached as a joint exercise, with the full involvement of the farrier. Interference injuries, such as scalping, that suddenly begin to occur regularly in a horse previously unaffected can be an early sign of gait alteration reflecting pain, and the horse's action at the walk and trot should be carefully evaluated.

The following approaches may be helpful.

Brushing Injuries of the Hindlimbs

Hindlimb brushing injuries are caused by the contralateral foot in flight and produce cuts on the medial aspect of the fetlock or the proximal aspect of the pastern. Most of these horses toe out and are base narrow, and some swing the foot inward during protraction at walk and trot. Traditionally three-quarter round shoes have been used, with the medial branch missing. Over time, however, this shoeing results in progressive collapse of the medial hoof wall, pushing the limb even further out of line, and brushing may actually increase. An alternative is to use light steel or alloy plates behind. This lowers the weight of the foot and often stops the problem. If this fails, we use a 2-cm lateral trailer on the shoe. Half-round shoes are always a help because they remove the cutting edge if interference does take place.

Brushing Interference in the Forelimbs

Brushing in forelimbs is difficult to treat. Affected horses usually toe out considerably from distal to the metacarpophalangeal joint and are base narrow. Horses often first show interference when galloping at speed, and injury causes substantial hemorrhage and swelling over the medial PSB. This swelling then makes future interference even more likely, and a downward spiral begins. The steps I usually take involve careful correction of medial to lateral hoof imbalance by the farrier, rest and antiinflammatory treatment to reduce swelling, and application of closely fitted half-round section shoes. Topical application of dimethyl sulfoxide containing flumethasone is indicated unless there is an open wound. If a full-thickness skin

wound is present, topical antiseptics and systemic antibiotic treatment may be indicated to prevent undue swelling at the site. Ultrasonographic examination sometimes reveals a subcutaneous seroma, which responds well to needle drainage and injection of a small amount of corticosteroids (dexamethasone, 2 to 4 mg).

Protection of the site of injury on return to training with a thin layer of cohesive exercise bandage can help, but great care should be taken in applying this type of bandage because the lack of padding can all too easily produce a bandage bow (bind). Even with all these measures, it is not uncommon for affected horses to suffer repeated intermittent problems throughout their careers.

Scalping, Forging, and Overreaching

Scalping, forging, and overreaching are produced by the hind foot arriving in the site occupied by the front foot too soon in the gait cycle.

Scalping produces cuts on the dorsal aspect of a hindlimb pastern, too dorsal to have been caused by the contralateral limb. Scalping is caused by the tip of the front shoe striking the front of the advancing hind pastern, as the horse just misses forging. Such injuries often are avoided by a four-point trim or shortening the toe and using a rolled-toe shoe in front to speed breakover fractionally, thus getting the front foot out of the way by the time the hind foot arrives. If this alone fails, then using a light steel or alloy plate with a square toe in front and heavy steel shoes behind often eliminates the problem. The same measures are used to reduce true forging, when the hind shoe strikes the tip of the front shoe, producing the characteristic steel-on-steel noise from which the name is derived. Forging can be more common when horses jog on a soft synthetic or sand surface, which "holds" the front foot and prevents its early clearance, and rolling and damping these track surfaces before use can help. Overreaching, when the hind toe strikes the bulb of the front heel, can be approached in the same way. Overreach boots can help but can only be used in slow work. Overreaching is most common when the horse is fresh and being restrained hard in its exercise or is being exercised in deep sand, preventing easy limb clearance. For this reason these horses can be helped by judicious use of mild sedation before exercise (10 to 25 mg of acetylpromazine orally, 30 minutes before exercise) and by exercising on a nonimpeding surface. In many horses all these measures can cease as the horses become fully fit.

TEN MOST COMMON LAMENESS CONDITIONS

The following are the 10 most common lameness conditions; these are discussed in detail in this section.

1. Foot-related lameness
2. Suspensory desmitis
3. Fetlock lameness and subchondral bone injuries to the distal aspect of the third metacarpal/metatarsal bone
4. Lameness associated with the middle carpal joint
5. Lameness subsequent to bacterial infection
6. Stress fractures of the long bones (third metacarpal bone, tibia, and humerus) and pelvis
7. Exostoses of the second and fourth metacarpal/metatarsal bones (splints)
8. Undiagnosed hindlimb lameness

9. Fractures of the proximal phalanx and condyles of the distal aspect of the third metacarpal/metatarsal bone
10. Lameness associated with the tarsometatarsal joint

Foot-Related Lameness

TB feet are usually thin soled, and most racing TBs have a pain response to hoof testers, even in the absence of genuine lameness. To minimize laminar bruising, good shoeing technique is essential, and horses should not be exercised on a surface that is too firm. Medial-to-lateral foot balance is also vital but often neglected. Farriers often are expected to shoe in the dark of the early morning, with the horse loose in the stable on deep bedding. This often leads to poor visual assessment of foot–pastern axis and balance. Clinicians should help farriers to change this attitude in favor of a system that allows these skilled professionals to achieve their potential. Such a change involves providing staff members to lead out and hold the horses for the farrier to inspect.

Bruising usually is diagnosed when the horse shows an exquisite pain response to hoof testers in a fairly localized area, but no obvious tract leading to the deeper structures. Careful paring with a hoof knife often reveals pink discoloration in the horn layers immediately above the area of the bruise. Removing the shoe and applying a poultice to the foot for a day is usually successful in managing this condition. If the horse is close to a race and time is of the essence, the foot is iced morning and night in an attempt to decrease the pain associated with the bruise. Once the pain is clearly found to be only from the bruising and no pus pocket has formed under the sole, poulticing is stopped to dry up the sole again before shoeing. If foot lameness is associated with infection, then draining the subsolar abscess is mandatory. Although traditional textbooks talk about radical curettage and establishing sufficient drainage, in the racing TB removal of too much horn is associated with an extended period of lameness because of laminar damage and pain from exposed soft horn. Initially the hole to the pus pocket should be as small as possible. Once drainage has been established, hoof testers can be used to expel pus and to pull in soaking agents or hydrogen peroxide. The hole often can be enlarged using a bent 16-gauge needle. The foot usually is soaked then in warm salt water for 10 minutes morning and night and in between is wrapped in saline-soaked cotton wool dressing contained within polyethylene. Walking these horses twice a day if the degree of lameness permits is a good idea to encourage extrusion of the pus, which leads to quicker return to full work and decreases the risk of rhabdomyolysis on return to training. Some infections within the foot are infuriating because although an exquisite pain response occurs and a clear penetration tract leads into the foot, blood in the sensitive laminae is reached before the infected focus is found. The horse then usually resents further digging in the sensitive laminae. Radiological examination is justified in these horses to rule out infectious osteitis of the distal phalanx, usually evident as a radiolucent area. This condition, if confirmed, is treated by radical curettage after sedation, local nerve blocks, and application of a tourniquet. A treatment (hospital) plate is then applied.

Traumatic corns can be one of the most frustrating conditions with which to deal. Affected horses usually have a long-toe, low-heel conformation and inwardly collapsing

heel bulbs. Intense pain occurs when hoof testers are applied across the seat of the corn, and yet exploration simply reveals subsolar blood pockets or bleeding tissue. When these are exposed, localized prolapse of the sole may occur at the seat of the corn. These horses take a long time to regain soundness and normally are shod with a bar shoe to bridge the weight bearing from the nonaffected heel to the wall of the other quarter. The horse should be kept in walking exercise only for at least 2 weeks to allow some horn growth before an attempt at retraining. Training and racing on hard surfaces is contraindicated, which can be realistic advice in the United Kingdom. These horses may be more difficult to manage if sold to train on the tracks in North America. The farrier should be involved in attempting to bring up the heel angle in these flat-footed horses, and the four-point trim is often helpful in achieving this quickly. Medial-to-lateral balance should be checked because traumatic corns often occur on the lower aspect of a heel of a horse that has been allowed to become unbalanced. This seems to occur because of second contact concussion as the foot strikes the ground in a biphasic manner, which is corrected by lowering the longer side of the heel to make sure that the foot strikes the ground evenly.

Sometimes a breach in the horn at the seat of the corn allows infection to enter, producing an infected corn. The condition often is linked to swelling and pain or even discharge of pus at the bulb of the heel above the corn. Drainage, poulticing, and remedial shoeing are the standard treatments.

For lameness associated with the horse being pricked by the farrier, with or without development of infection, use of a glue-on shoe when the horse is reshod after the problem has been resolved is sometimes a good idea. Most farriers shoeing racehorses are extremely skilled, and if they have managed to puncture the sensitive laminae during a routine shoeing, the cause is usually because the horse has extremely little wall outside the white line. The direct glue-on technique, using a normal alloy racing plate stuck directly to the sole without nails, allows the horse 3 to 4 weeks of extra horn growth before further nailing is done. The more traditional tab-glue shoes are less satisfactory because the shoes tend to become loose and the horse's foot shape may change. This is not the case with direct glue-on shoes. Horses that repeatedly lose shoes and have increasing wall avulsion and damage are treated best using direct glue-on shoes to allow time for wall recovery. More recently another type of glue-on shoe has been developed by farrier Rob Sigafoos (the Sigafoos shoe). This is constructed incorporating a collar of strong synthetic fabric into the structure of the shoe, which is glued directly to the dorsal wall of the hoof. The advantages with this shoe are that the heel bulbs are not bound in and can expand over the shoe, and that the shoe can be set properly under the foot in a normal position. Horses have trained and raced with success in these shoes.

Suspensory Desmitis

The forelimb SL can be injured at any location, but PSD is most common in a young racehorse. PSD is often bilateral, although the lameness observed is almost always unilateral. PSD is characterized by weight-bearing lameness of grade of 1 to 3 of 5, which seems to disappear rapidly after periods of rest. Even 24 hours of box rest often renders

these horses sound. However, within an exercise period, the lameness is typified by becoming worse the more the horse does (warms into the lameness). Horses with PSD often show pain when the SL is squeezed between the thumb and the back of the McIII with the limb flexed. The veterinarian should start at the apex of the PSB and work along the SL, squeezing it against the bony structures of the limb. The response should be compared with the contralateral limb. Most normal young TBs show some degree of tenderness to palpation of the SL, although unbroken and untrained horses of the same age usually do not. This may indicate that many racehorses suffer a degree of PSD during early training in the absence of observable clinical signs. Lesions of the origin of the SL can be present without pain on palpation because it is difficult to apply accurate digital pressure in the proximal metacarpal region.

Local analgesia is discussed on page 1001. When performing subcarpal analgesia, the needles should be applied to the syringe before injection to prevent the introduction of air into the fascial planes, which can preclude later ultrasonographic examination. This air appears as a hyperechogenic band between the SL and the accessory ligament of the deep digital flexor tendon, obscuring evaluation of the SL.

The other common predilection site for injury of the SL is the interface of the distal aspect of a branch and the ipsilateral PSB. These lesions usually occur when the horse starts fast exercise. In horses with conformational defects, the same site can be affected in both forelimbs. For example, in a horse with offset carpi and toed-in conformation, the lateral branch of the SL and the lateral PSB are affected. Typical radiological changes of sesamoiditis are seen with clear disruption of the SL/PSB interface. Central hypoechoic lesions are identified by use of ultrasonography, along with irregularity of the PSB surface and even fragment avulsion. The SL branches often are enlarged palpably, but ultrasonographic imaging often reveals this to be a zone of periligamentous fibrosis, rather than true swelling of the branch itself.

Horses with PSD are confined to box rest for 2 to 4 weeks until clinically sound and then walk on a horse walker for 4 to 6 weeks, followed by 1 month of walking and trotting exercise. Ultrasonographic reassessment is recommended to determine whether the horse should start alternate-day cantering exercise or continue trotting for another month. Horses with distal branch lesions may have a guarded prognosis if substantial sesamoiditis exists. Most of these horses are taken out of training altogether as 2-year-olds and given the same rest program as horses with PSD. At the end of the period of controlled exercise, the horse usually is turned out and brought back in at the end of the year for further education, before resuming training as a 3-year-old. This distal branch/proximal sesamoid bone surface interface lesion is one of the few clinical situations in which I have been convinced that extracorporeal shock wave therapy (ESWT) has improved prognosis and reduced reinjury rate. I use weekly treatments of 3000 to 4000 shocks using a dual lithotripsy machine in ballistic mode at 4 Bar for 6 weeks in conjunction with controlled exercise.

Most young racehorses with PSD have an increase in the dorsopalmar thickness of the proximal aspect of the SL to greater than 1 cm, and irregularity of contour, with bulging of the normally flat palmar border (palmar bowing),

detectable by ultrasonography. The fiber pattern may be heterogeneous. Ultrasonographic monitoring of these lesions may reveal a decrease in size of the SL, with more linear borders as healing progresses. However, in many horses, the SL never returns to normal. Exercise level is increased when the ligament shows good echogenicity, although it still may be enlarged. Some horses seem to have long-term hypoechoic lesions within the SL that do not change with further rest.

Less commonly, a unilateral, acute, focal core lesion occurs in the SL after a race or gallop associated with lameness, swelling in the subcarpal region, and an exquisite pain response to palpation. Occasionally the SL seems to split, with the most dorsal surface being linearly avulsed, presumably by fluid or hemorrhage. This results in considerable thickening and striation of the SL.

The prognosis for mild to moderate PSD in 2-year-old TBs is good, but the prognosis is more guarded in horses with acute core injuries. Some of these horses take 4 to 5 months before they are able to withstand training and have a risk of reinjury. The prognosis in older horses is also guarded to poor.

In a 3-year-old horse that had PSD at 2 years of age, mild lameness may recur as training speed increases, in the absence of any real changes that can be identified using ultrasonography, radiography, or scintigraphy. This lameness always can be abolished by subcarpal analgesia. These horses with subcarpal "ache" often can be managed by administration of 5 to 10 mg of triamcinolone acetonide in 3 mL of local anesthetic solution, injected in the same site as a subcarpal block. Lameness often is abolished for long periods after this treatment, without apparent degeneration of the SL, even with continued training. It is vital to complete a full diagnostic evaluation before treatment in these horses to eliminate the possibility of training horses tolerating incipient catastrophic lesions under the influence of corticosteroids. For those working under jurisdictions that do not allow the presence of drugs at race time, such as in the United Kingdom, clinicians should be aware that the detection period for triamcinolone acetonide at this site can approach 30 days, and shorter-acting agents such as dexamethasone may be preferred.

Fetlock Lameness and Subchondral Bone Injuries to the Distal Aspect of the Third Metacarpal/Metatarsal Bone

All racehorses begin training when they are skeletally immature and relatively weak, and this leads to frequent damage to the pressure points on either side of high motion joints. Lameness can result from impingement lesions at the site of contact between the distal extremity of the McIII and the proximal eminence of the proximal phalanx as the fetlock sinks in hyperextension. Lesions include damage to the cartilage, synovitis, osteochondral fragmentation, or very often a combination of all three. The typical early sign is of a distended fetlock with pain on flexion and a mild degree of lameness. Radiological examination often reveals new bone at the proximal extremity of the sagittal ridge of the McIII and remodeling or minor fragmentation of the proximal eminence of the proximal phalanx. We should resist the temptation to "fix" these joints in a 2-year-old by intraarticular medication because heat and inflammation

tell us that the joint is having problems. These horses need some time. External application of ice, in conjunction with reduction of exercise to jogging for a couple of weeks, with or without the use of oral NSAIDs, gives these horses some chance to recover. The treatment may need to be repeated two or three times before the horse can train without trouble. There is often substantial pressure to keep such horses in training, with a request for intraarticular corticosteroid treatment. We all succumb to this pressure on occasion, but we should always point out to the trainer and owner that after corticosteroid administration, any healing processes will cease for a considerable time. The pain response, which is protecting the joint from overuse, will also be abolished or diminished, allowing more damage to occur. There will be a price to be paid later in the horse's career. In an older horse, ongoing OA can often be traced back to an early interventional therapy, followed by a cycle of continued intraarticular treatment. There is often an ever-diminishing response to treatment until there is an end-stage joint with cartilage wear, fibrillation, or collapse, along with severe pathological change in the subchondral bone.

Subchondral bone injury is an extremely common cause of lameness in young TBs and is vastly underacknowledged. Subchondral bone pain seems to be increasingly implicated in much joint-related lameness in other classes of horses (e.g., navicular syndrome, tarsal pain, and third carpal bone pain). In the young TB, subchondral bone injuries in the distal aspect of the MtIII and the McIII often are linked to bilateral or quadrilateral lameness, which limits performance. Horses with bilateral subchondral bone injuries of the distal aspect of the MtIII fail to push from behind at exercise. Often these horses appear to bunny hop for the first section of canter. The rider reports that the horse feels wrong behind and does not perform as well as it previously did. The clinical history (see page 997) and response to diagnostic analgesia (see page 1001) have been described. With American-bred horses, equine protozoal myelitis (EPM) is an important differential diagnosis because the clinical appearance can be similar. Onset of clinical signs can be delayed, so that a yearling bred in America and sold in Europe could have EPM.

Subchondral bone injuries are extremely difficult or impossible to identify radiologically. If lesions are visible radiologically, these are usually end stage, and horses warrant a guarded prognosis (see Figure 107-5). These lesions usually represent necrosis and collapse of subchondral bone and are visible as a crescent-shaped radiolucency in the middle of the lateral condyle of the MtIII, seen on flexed plantarodorsal or flexed dorsoplantar images (see Figure 107-4, B). Increased radiopacity of the lateral condyle also occurs and is most visible on a lateromedial image. Deliberate overexposure may be necessary to demonstrate a triangular region of increased radiopacity just palmar/plantar to the midpoint of the articular surface (Figure 107-7). All racing TBs seem to develop some degree of sclerosis in this site as a normal physiological response to loading from the PSB as the limb assumes full extension. MRI examination reveals changes associated with dense mineralized subchondral bone and sometimes focal areas of increased signal intensity in fat-suppressed images, which may reflect microfracture, fibrosis, or bone necrosis (see Figure 107-6).

Fig. 107-7 • Post mortem specimen of the distal aspect of a third metatarsal bone from a horse with plantarolateral focal increased radiopharmaceutical uptake seen on a bone scan. Lateral is to the left. The specimen was collected when the horse was euthanized for unrelated reasons. The area in the center of the plantarolateral aspect of the condyle is dark, and the cartilage surface is irregular (arrows). Histopathological sections cut through the site revealed abnormal irregular and necrotic subchondral bone. Compare with the lesion in Figure 107-5, C.

On scintigraphic examination, these stress injuries are remarkable because increased radiopharmaceutical uptake (IRU) is focal in nature and markedly increased. On a plantar image, IRU in the MtIII is mistaken easily for IRU in a PSB because the shape of the lesion is similar to that bone. However, on a lateral image, the PSBs can be seen clearly plantar to the region of the IRU, localized within the condyle itself (Figure 107-8). In the forelimb, subchondral bone injuries in the metacarpophalangeal joint seem to occur most commonly in the medial condyle, but can also be present in the lateral condyle or both. Horses usually have bilateral lameness and trot with the head held low with a short, stumbling gait as they try to get off each weight-bearing limb as fast as possible. If all fetlock joints are injured, a horse may refuse to trot and attempt to break into a slow, rolling canter as speed increases. Lameness often becomes apparent in the contralateral limb after local analgesia of one metacarpophalangeal/metatarsophalangeal joint. Radiological examination is often unremarkable, but scintigraphy confirms focal IRU in an active early lesion. Use of flexed dorsal and flexed lateral scintigraphic images is helpful in pinpointing the exact location of the lesion, particularly in the front limb (see Figure 107-8). In the more chronic stage, there may be only mild IRU, yet the pain and lameness can be more intense. We should not forget that the mere presence of mild IRU does not necessarily mean painful and vice versa.

Treatment is difficult, and we have no protocol that results in uniform resolution of lameness. Many different treatment regimens have been used, including intraarticular injection with hyaluronan or corticosteroids; systemic medication with isoxsuprine, aspirin, polysulfated glycosaminoglycans, or tiludronate; and rest alone.¹⁶ Often the lameness disappears rapidly after the instigation of rest but returns when the horse resumes fast galloping speed. Although some horses have been able to perform without further problems, predicting which horses may respond

Fig. 107-8 • A, Plantar delayed (bone) phase scintigraphic image of horse with bilateral stress injuries to the lateral condyle of the third metatarsal bone. The shape and distribution of the increased radiopharmaceutical uptake (IRU; *arrows*) easily can be mistaken for that associated with the lateral proximal sesamoid bone (PSB). **B,** Lateral delayed (bone) phase scintigraphic image of the same horse. If there is doubt as to the exact location of the IRU, a flexed lateral image (**C**) is useful in moving apart the PSB and the plantar aspect of the lateral condyle. This clearly shows the IRU to be situated in the plantar aspect of the condyle (*arrow*) rather than the PSBs, which are moved away from the joint in this image. (Courtesy Sue Dyson, Animal Health Trust, Newmarket, England.)

favorably is not possible. However, those with subchondral lucency and sclerosis rarely remain sound. This does not mean that these horses cannot perform, and many racehorses seem to withstand training despite lameness. However, this may be a performance-limiting problem that directly interferes with racing ability and determines the level at which the horse can compete.

Because horses with advanced lesions rarely return to sustained soundness, it is advisable to stop hard training as soon as the condition is noted in a 2-year-old and allow 3 months of rest. This is not a guarantee that the problem will not recur at 3 years of age, but going on with training these young horses in the face of this lameness seems illogical. Many horses can be trained at 3 years of age without problems. When the clinical syndrome appears in a horse

aged 3 or more for the first time, the prognosis is much worse than when subchondral bone lesions occur in a 2-year-old and the horse is allowed to rest. In an older horse, end-stage pathological damage in the affected condyle is more common. These horses may well have been trained through the problem at 2 years of age, with a low-grade bilateral lameness that was not recognized.

Some horses first show hindlimb lameness associated with the lesions in the lateral condyles of the MtIII after a race on unsuitably firm ground. They are described as “jarred up.” Although the clinical appearance of a jarred-up horse has long been recognized, no precise definition of the syndrome has ever been made. The syndrome may well represent multifocal subchondral bone pain. Affected horses may never regain normal action. The reasons why some horses become progressively lamer whereas others can race with success and maintain a steady-state lameness are not understood.

A few horses with subchondral bone injury have been examined at post mortem (see [Figure 107-7](#)). The degree of damage to the subchondral bone at the injury site easily explains why some horses are untrainable. We need to understand why some horses develop these lesions whereas others do not, whether the type of training surface may be a predisposing factor, what pathological mechanisms are involved, and why these lesions produce pain. Ideally, we also need to track some young TB horses using repeat MRI scans from the time they are broken right through training to see when these lesions develop and what impact they have on gait and race performance.

Lameness Associated with the Middle Carpal Joint

Several distinct syndromes are associated with the middle carpal joint. One of the most common syndromes is exemplified by a 2-year-old in early training that develops an increasingly short, choppy gait at the trot. The limbs are held abducted during the protraction phase, and the carpi are barely flexed. This gives a stiff, rolling action. Often the horse has bilateral middle carpal joint effusion and pain on carpal flexion. Injection of local anesthetic solution into one middle carpal joint produces lameness (grade 1 to 2 of 5) in the contralateral limb. The gait changes so that the desensitized limb is often brought back toward the midline. Some of these horses have mild increased radiopacity of the third carpal bone, seen on a skyline image, but others have no detectable radiological abnormality. These horses probably are suffering from pain produced by concussion of immature cartilage and excessive torsion on untrained ligaments within the carpus, and should be given rest. If excessive effusion occurs, the joint may be drained and medicated with triamcinolone acetonide (5 mg) and hyaluronan, but only if rest is to follow. Non-steroidal antiinflammatory drugs (NSAIDs) may be administered for the first 4 or 5 days of rest. Most horses are restricted to box rest for 1 month, followed by walking exercise for 2 weeks, followed by 1 month of trotting before resuming full training. Many horses never show lameness again during the second introduction to exercise loading.

The second syndrome, which may include some horses in the first category if training has continued, involves development of more severe sclerosis in the third carpal bone and remodeling of the distal aspect of the radial carpal bone. Focal overloading of the third carpal bone results

from a conformational defect (offset carpi with toe in is the worst) or from a mismatch between loading of the limb and time allowed for adaptation. These horses are usually bilaterally lame; often one lame limb dominates, and contralateral limb lameness is only recognized when the lamest limb is blocked. Radiological signs include increased radiopacity in the radial fossa of the third carpal bone seen on the skyline image, associated with local areas of rarefaction around the nutrient foramina or with small comma-shaped fissure fractures extending from the dorsal aspect of the third carpal bone. Further training of these horses risks development of a full sagittal fracture (see [Figure 107-2](#)).

Despite statements to the contrary in the literature, I believe that the early sclerotic changes in the third carpal bone are reversible after a period of box rest. However, there seems to be a certain degree of pathological damage from which there is no return. Once the radial fossa becomes completely devoid of trabecular detail and has a "ground glass" appearance radiologically, the changes are often permanent. These lesions often are associated with recurrent lameness each time the horse reaches racing speed. Therefore identifying increased radiopacity of the third carpal bone at an early stage is vital. Screening radiographic examinations of the third carpal bone in a 2-year-old may be useful before starting full race-speed galloping. Without radiological information, lameness may be the first indicator of sclerosis, which may already be advanced.

Lame horses with third carpal bone sclerosis are confined to box rest for 2 months, followed by 1 month of walking exercise. Radiographic examination is then repeated. I advise that these horses are not trained with a view to racing at 2 years of age, although they may reenter the training environment so that they acclimatize to respiratory disease and other management problems that might influence the 3-year-old career.

Problems related to the distal aspect of the radial carpal bone are also common, associated with lameness and distention of the middle carpal joint capsule. Radiological abnormalities include spur formation on the distal aspect of the radial carpal bone and radiolucent changes in the same site leading to modeling of the dorsal margin. This usually leads to or is associated with coexistent secondary sclerosis of the opposing third carpal bone because the load becomes borne by the medullary bone, instead of the weight-bearing pillar of the dorsal cortex. These radiological abnormalities result from overloading the carpus, leading to bone stiffening, cartilage damage, and secondary OA. Debate exists over whether spurs should be removed surgically. OA of the middle carpal joint is already established. Although removing the spur is logical, it is not curative, and the horse will still require treatment the following season. With cheap horses and in yards where money is tight, many horses with mild carpal OA can be treated once by intraarticular medication with hyaluronan and triamcinolone acetonide, followed by 4 to 6 weeks of rest and a graded return to exercise.

If a chip fracture occurs, then removal of the fragments is probably still mandatory. One should explain to the owner and trainer, however, that the horse has preexisting OA that will persist after surgery and that further problems should be anticipated the following season.

The antebrachiocarpal joint is more forgiving than the middle carpal joint in the amount of pathological change

that can be seen radiologically in the absence of clinical signs. Large fragments can be removed surgically with a favorable prognosis for horses the following season. Some horses can continue to train and race without obvious impairment even with chip fractures left in situ in this joint.

A small group of horses with middle carpal joint pain remains in which lameness recurs after periods of rest, despite absence of radiological changes. These horses often have unilateral lameness associated with middle carpal joint effusion. Some of these horses have tears of the palmar intercarpal ligaments. Response to conservative treatment often is disappointing, and even after prolonged periods of rest, lameness recurs as soon as work intensity increases. I normally medicate these horses with hyaluronan and corticosteroids, but in the absence of a firm diagnosis, this empirical treatment is illogical and usually unrewarding. Diagnostic arthroscopy probably is always indicated in these horses but is also often unhelpful in producing a permanent cure. We should also always be aware that local anesthetic solution in the middle carpal joint can abolish pain arising from the SL, carpal ligaments, and many other structures, and it may be very simplistic to assume a positive middle carpal joint block means we have problems only in the middle carpal joint. MRI examinations of some of these horses have been carried out recently and reveal a catalog of abnormalities in structures all around the site of the block.¹³

Lameness Subsequent to Bacterial Infection

Bacterial infection in a limb of a horse can cause a degree of pain greater than almost any other injury, including a displaced fracture. Although wounds in any part of a limb can become infected, leading to an obvious swelling and lymphangitis, some discrete syndromes in the racehorse deserve mention.

Staphylococcal Abscesses on the Palmar Aspect of the Metacarpophalangeal Joint

Horses exercising on sand, synthetic, or wood chip surfaces seem to be prone to bacterial infections around the ergot that produce small, focal abscesses, which can be difficult to find if the horse has a winter coat. The horse often initially points the limb, is severely lame (grade 4 of 5), with swelling on the palmar aspect of the metacarpophalangeal joint. Manipulation of the joint is resented. The abscess can mimic the appearance of an infected joint and must be differentiated because synoviocentesis inadvertently may introduce infection into the joint. Careful evaluation shows that the metacarpophalangeal joint capsule is not distended. By working through the hair coat with the fingernails, localizing the point of a small abscess is often possible. The horse shows a severe pain response, and a pink porelike hole may be observed discharging serosanguineous pus. Bacteriological culture almost invariably results in the growth of a hemolytic *Staphylococcus aureus*.

Treatment is by external application of kaolin paste or a similar open poultice, combined with systemic antibiotic therapy along with NSAIDs and forced walking exercise. Horses are normally sound after 12 to 24 hours, and if this is not the case, then the diagnosis should be reestablished. Bandaging should be avoided because the limb often continues to swell and the bandage may become

constricting, which can lead to ischemic necrosis and sloughing of the skin.

Focal Peritarsal Cellulitis

Focal peritarsal cellulitis is a syndrome that appears to be related to the architecture of lymphatic drainage and is characterized by acute-onset severe lameness (grade 4 or 5 of 5), often with a shocklike state, hyperventilation, and sweating.¹⁶ Rectal temperature is elevated (39 to 40° C). Clinical examination of the limb reveals an exquisitely painful area on the dorsomedial aspect of the hock with focal swelling (Figure 107-9). Brushing this area lightly with the fingertips usually causes the horse to stagger sideways and abduct the limb sharply to get away from the pain. Almost always a small skin lesion of some sort is evident in the distal part of the limb, through which the initial infection may have entered.

Although the horse is severely lame in the stable, if forced to walk, the lameness usually improves after a few steps, and the horse bears weight reasonably well. The focal swelling on the medial aspect of the tarsus appears to be linked to a nidus of lymphatic drainage because the swelling is so consistently positioned. The pain is so great because of involvement of the retinaculum and fascia immediately above and beneath the site, causing a compartment-like syndrome. Some North American clinicians describe emergency surgical drainage of these abscesses, with or without fasciotomy. However, conservative treatment using antibiotics (oxytetracyclines or ceftiofur), along with NSAIDs

Fig. 107-9 • A horse with focal peritarsal cellulitis. There is tight focal distention caused by swelling associated with infection in the deep fascia beneath the skin, retained at either extremity of the tarsus by the retinacular ligaments. This produces a profound degree of pain for the horse.

administered morning and night, and forced exercise several times daily is usually adequate.

Often within 24 hours the swelling changes from a small egg-sized swelling on the medial aspect of the hock to involve the entire distal part of the limb. Swelling gradually resolves with exercise over the next month.

A great risk of laminitis in the contralateral limb exists in the early stages because of the combination of severe lameness in the affected limb and toxin production from the abscess. Therefore it is vital that the horse is stabled on deep bedding during its initial treatment and that regular exercise is encouraged despite obvious lameness in the affected limb.

Axillary and Scrotal Intertrigo Infections

Horses are affected by skinfold infections, particularly in the axilla and groin. The infection begins in the fold of skin and causes an exudative, purulent dermatitis. The swelling of the affected region results in more occlusion and development of anaerobic infections deep in the skin folds. Affected horses often stand with the limb abducted and appear as if they have a proximal long bone fracture. Because the swollen skin folds close themselves off, these lesions can be missed unless the limb is pulled away from the body to expose the raw pink exudative dermatitis. Treatment is by systemic administration of antibiotics and analgesics and topical cleansing of the affected area with a debriding agent, followed by application of an antibiotic ointment. Fusidic acid creams are often effective because most of these infections involve staphylococci. Topical treatment often requires profound sedation of the horse so as to be carried out safely because of the pain involved. Exercise should be limited to a short period of handwalking, until the edema of the skin folds of the axilla subsides, because walking produces friction that makes the condition worse. Less commonly the area between the scrotum and the medial aspect of the thigh can be involved, especially in horses exercising on dirt or sand. Affected horses walk in a crouching gait, with abduction of each hindlimb during protraction. Once the acute infection has resolved, daily use of a talcum powder designed for use in babies is helpful in avoiding recurrent chaffing of the edematous skin during exercise for the first couple of weeks.

Stress Fractures of the Long Bones and Pelvis

Post mortem studies carried out on racehorse fatalities in California have revealed that many horses have evidence of previously undetected stress fractures of the long bones. We have been aware clinically of these fractures for some time, particularly when they became complete and displaced in horses in training. With the advent of scintigraphy, the early diagnosis of these stress fractures increased.

Certain rules apply to all stress fractures in the TB. Fractures usually occur after repeated cyclical loading of bone over time rather than as an acute incident. Lameness itself may be *acute* in onset, as the bone reaches the stage where it can no longer bear weight and the cortex begins to collapse. However, because the lesions are chronic in nature, radiological signs that we tend to link to bone healing and remodeling, such as periosteal new bone formation, irregular ill-defined lucencies in the cortex, and occasionally cortical displacement, may be detectable at the onset of lameness. Because stress fractures result from

repeated focal overloading, they tend to occur in predilection sites in the bone, reflecting the architecture of that bone and the manner in which weight is borne during locomotion. The repeatability of these sites makes looking for these injuries on radiographs more straightforward.

Skeletal bone seems to detrain almost as effectively as it can be trained. For this reason, any horse that has been removed from training for longer than 3 weeks should be given sufficient time to allow reconditioning of the skeleton on return to training. Stress fractures may occur in horses of any age if they have been removed from training for a period of more than 1 month and have been returned to cantering exercise too rapidly.

Periostitis of the Dorsal Cortex of the Third Metacarpal Bone (Sore or Bucked Shins)

Sore shins are a common problem in 2-year-old racehorses or in older horses that have not reached race speed previously or have had a long layoff. Most of these horses are not shown to a veterinary surgeon. The stable staff and trainers know how to recognize sore shins and treat them in a variety of traditional methods. It is advisable to restrict the horse to trotting until the area is no longer painful to light fingertip pressure with the limb flexed. The horse is then reintroduced to the exercise level one step beneath the level that produced the soreness. This speed is maintained for 1 month before increasing. If the shin soreness returns as speed increases, the cycle is repeated.

Rarely, more invasive therapy is required for horses that have three serial episodes and for which normal management strategies have failed. The shin is pin fired under local analgesia, and the horse is walked for 2 weeks and then trotted for 2 weeks before gradually increasing speed work. Freeze-firing is a local temporary neurectomy only and confers no long-term benefit. The shin is a barometer of what is going on in the rest of the skeleton, and when sore the shin indicates that the skeleton needs more time to adapt. Freeze-firing simply lets us ignore this and allows the horse to develop real damage elsewhere. This subject is controversial, and the views expressed here are not shared by all veterinarians.

Fracture of the Dorsal Aspect of the Third Metacarpal Bone

Fracture of the dorsal aspect of the McIII presents as an extension of the sore shin complex. When a true stress fracture (dorsal cortical fracture) is present, the pain to palpation usually is localized to one area rather than being distributed across the entire surface of the shin. Normally a periosteal callus is present at the site of the fracture, causing a bump on the surface of the McIII. Radiographic examination should include unorthodox lesion-oriented oblique images because the fracture lines are often extremely difficult to see, particularly in the acute phase of the injury. Horses are usually slightly lame, but continued training results in an increase in lameness after each exercise period, which reduces rapidly. A lame horse with focal periostitis that is painful to palpation should be considered to have a stress fracture at that site, even if the fracture is not visible radiologically. Treatment is by rest, which can include walking exercise. These injuries normally take about 1 month to heal, after which light training may begin, but 3 months should elapse before full training speeds are achieved. If the injury has progressed to a clear tangential

fracture line in the cortex, some veterinarians recommend surgical drilling (osteostixis), or even screw insertion across the fracture line, to encourage healing. This has never been necessary in my experience. ESWT is also used to treat horses with this type of fracture, but its clinical efficacy remains to be proved. Normally early diagnosis allows full healing with conservative treatment alone.

Tibia

Stress fractures of the tibia are one of the most common causes of hindlimb lameness in 2-year-old racehorses in race training. In the seasonal racing calendar, when yearlings enter training in October or November, peak incidence of tibial stress fractures is in April or May as speed work increases. The tibia has three main predilection sites. The most common in naive horses entering training for the first time is the proximolateral cortex, 7 to 8 cm distal to the proximal articular surface of the tibia. Stress fractures in this site are visible radiologically as poorly defined callus, often associated with an oblique fracture line in the cortex itself. The second common predilection site, often seen in a 3-year-old or in a 2-year-old in more advanced training, is in the caudal distal cortex, 10 cm proximal to the tarsocrural joint. On radiological examination endosteal callus can be seen as a subtle sunburst of increased radiopacity extending forward from the caudal cortex on a lateromedial image. On a caudocranial image, a lucent line is usually visible, surrounded by an area of increased radiopacity in the middle of the distal aspect of the tibia. The third common site is the middle of the medial cortex. In this site, the injuries usually are seen as periosteal and endosteal new bone formation only, and fracture lines are visible only rarely.

Occasionally a complete, comminuted displaced fracture of the tibia can occur during racing or training. The prognosis in these horses usually is hopeless. In Newmarket complete tibial fractures occurring at exercise have almost disappeared following the advent of scintigraphy, suggesting that in the past some complete fractures were the end stage of chronic stress fractures, which are now detected early.

Diagnosis of tibial stress fracture is difficult because these injuries may not be affected by diagnostic analgesia. The typical history is of a 2-year-old being brought into faster speed exercise or of a 3-year-old that did not race at 2 years of age being prepared in the same way. The lameness is usually acute in onset and can be severe (grade 3 or 4 of 5) but usually diminishes rapidly with rest. Forced flexion of the hock and torsion of the tibia produce pain in horses with severe lameness (see [Figure 107-3](#)). Scintigraphy is ideal to confirm these lesions, but the degree of IRU seen in the middiaphyseal and distal metaphyseal sites is often mild, particularly if the horse is imaged early.

Treatment is by rest and a gradual return to training. The horse is restricted to box rest initially for 2 to 6 weeks depending on the severity of the radiological signs. Occasionally stress fractures of the tibia become complete and displaced during periods of convalescence after normal recumbency. The horse should be tied up by the head for the first 3 to 4 weeks if the weight-bearing ability of the tibia is severely compromised (for precautions, see [Chapter 49](#)). Less severely affected horses are exercised as soon as it is practical. If a treadmill or horse walker is available, horses

can be walked as soon as clinically sound, allowing a total healing period of between 2 and 3 months. Trotting exercise can be included in the second and third months.

Humerus

A horse with a humeral stress fracture has acute-onset forelimb lameness with features of proximal forelimb pain. The horse walks with a short cranial phase to the stride and circumducts the limb in protraction. Substantial weight-bearing lameness is evident at the trot. Horses often drag the toe of the affected limb in the bedding during protraction in the stable. The lameness rapidly diminishes, and in 2 days horses may be sound, only to go severely lame again after return to exercise.

Two main predilection sites exist for humeral stress fractures. Scintigraphic examination is ideal for diagnosis. One site is on the caudal cortex just distal to the humeral head, about 5 cm distal to the weight-bearing surface. Loose periosteal callus usually is visible, with increased radiopacity of adjacent bone and occasionally incomplete tangential fracture lines. The other site is the cranial or, less frequently, caudal cortex of the distal aspect of the humerus about 5 cm proximal to the elbow joint surface. A focal sunburst of callus usually is visible on a medio-lateral radiographic image, and a linear fracture line is sometimes seen. Treatment is as described for tibial stress fractures. Complete, displaced humeral fractures can occur in exercise, and horses have a hopeless prognosis.

Pelvis and Axial Skeleton

Fractures of the sacral wing of the ilium are often stress fractures and are described in detail elsewhere (see Chapter 49). Laminar stress fractures of the vertebrae immediately adjacent to the pelvis have been described.¹⁷ A full review of the scintigraphic appearance of stress fractures in the TB has been published.⁹ There is usually a unilateral lameness for which no other reason can be ascribed after routine diagnostic analgesia and survey radiography. Scintigraphic examination of these horses reveals focal IRU associated with the lumbar vertebrae on the same side as the lameness. Some horses simply show bilateral poor hindlimb propulsion, short stepping at the walk, and a hunched-up lumbar spine, coupled with poor performance without obvious lameness. Being certain that the laminar stress fracture is the cause of the reduced performance is difficult. However, if scintigraphy reveals an active bone injury in the spine, continuing full training cannot make sense, and these horses subsequently are allowed to rest. Although this lesion is described as widespread in the Californian pathological survey, the clinical presentation is uncommon. I have examined the lateral lumbar spine routinely in all bone scan images over a 2-year period and have not encountered the lesion as a common incidental finding.

Exostosis of the Second and Fourth Metacarpal/Metatarsal Bones (Splints)

Splints are more of a nuisance in a racehorse than a major problem. They are clinically obvious, and a sharp pain response can be elicited by squeezing the area. Splints normally are associated with lameness in the initial stages, although this can subside rapidly. Splint lameness is one of the few conditions with which lameness is often more

obvious with the affected limb on the outside of a circle. Splints are common in horses of 2 years of age but can occur in horses of any age, particularly if they experience a change in loading because of a different type of training surface or, paradoxically, a reduction in training workload, or a different angle of camber in the surface on which they are training. In many horses a fracture line is not detectable radiologically, but most horses with obvious exostosis formation associated with lameness probably do have fractures within the body of the bone, which often can be identified scintigraphically. Many of these "splints" will continue to show marked IRU for months or even years after clinical signs have settled. A period of stable rest with walking exercise is probably indicated until the horse is clinically sound. The horse then can recommence trotting for 2 to 4 weeks to allow the injury to heal fully. If pain on palpation and lameness immediately recur when the horse returns to exercise, then pin firing may be considered to encourage more aggressive callus formation. This is one of the few orthopedic indications in which firing achieves a good clinical result in most horses. Horses with displaced fractures of the distal aspect of the second and fourth metacarpal/metatarsal bones are treated by surgical removal of the distal portion of the bone.

Numerous comminuted fractures of the second and fourth metacarpal/metatarsal bones sometimes result from external trauma and heal surprisingly well. Many fragments may be identified by digital palpation with a gloved finger through an open wound and confirmed radiologically. Most horses with fractures heal satisfactorily with antibiotic treatment, bandaging of the wound, and stable rest. If infectious osteitis does occur with sequestrum formation and recurrent fistulation, then affected bone should be removed surgically. Open comminuted fractures of the fourth metatarsal bone can lead to infection ascending into the TMT joint and should be closely monitored.

Undiagnosed Hindlimb Lameness

Despite all our modern diagnostic aids, the cause of hindlimb lameness in a large number of horses remains elusive. Given the huge muscle mass involved in the hindquarters of the horse, some must have muscular origin and insertion pathological conditions, as well as pain from muscular overexertion. In human athletes, lameness is commonly linked to strains, tears, and cramps in the semi-membranosus and semitendinosus muscle groups and in the adductor and gluteal muscles. Horses are presumably no different. As yet, no definitive test appears to be available to confirm genuine muscle injury. Thermography is helpful in some horses but is disappointing in others, and only reflects changes in skin temperature. Increases in CK and aspartate transaminase levels, although pathognomonic for exertional rhabdomyolysis, do not seem to occur following genuine tears of muscle tissue. Presumably these tears result in little cellular disruption, the damage being more in the fascial planes and connective tissue.

If a horse remains undiagnosed after all available diagnostic analgesia and imaging modalities have been used, then the horse is confined to box rest with walking exercise only for 1 month. Most horses become sound in this period. The horse then returns to walking and trotting exercise for 1 month before resuming a normal ascending exercise program. Although admitting defeat and being unable to

give a definitive diagnosis is frustrating, one should try to avoid attributing a definite cause for the lameness if no evidence exists to support it. Trainers and clients should be educated to accept the fact that ascribing lameness to injury of a specific structure in every horse is not possible.

Fractures of the Proximal Phalanx and Distal Condyles of the Third Metacarpal/Metatarsal Bone

The most dramatic example of a proximal phalanx fracture is a split pastern that is a frequent injury, particularly in a 2-year-old racehorse as it enters fast work. The length and configuration of these fractures include complete sagittal fractures involving both articular surfaces, multiple comminuted displaced fractures, and incomplete fractures extending short distances from the proximal articular surface. Diagnosis is usually straightforward in horses with a complete fracture or an extensive incomplete fracture. With extreme injury, a horse pulls up severely lame during or at the end of exercise. With less severe injuries, horses may finish exercise apparently sound but become increasingly lame on return to the stable. The horse is usually not bearing weight by the time of examination. Pain always occurs on flexion of the metacarpophalangeal or metatarsophalangeal joint and on pressure applied with the fingertips to the proximal phalanx along its sagittal dorsal midline. Radiological examination is usually confirmatory.

Short incomplete sagittal fractures of the proximal phalanx can be notoriously difficult to see radiologically, when the fracture line only extends 1 or 2 cm into the bone. Clinical signs are of a severe lameness (grade 3 of 5) that rapidly improves so that the horse may be sound within 2 days. Flexion of the fetlock joint is usually not painful. Firm squeezing of the proximal dorsal surface of the proximal phalanx usually is resented, particularly approaching the proximal articular surface, and this is a reliable clinical sign. A horse with this type of fracture should be given box rest for at least 2 weeks before further radiography. Short, incomplete fractures easily become complete comminuted fractures if a horse is exercised after 2 weeks of rest because the fracture weakens by normal osteoclastic activity. Therefore although the horse may be sound, a premature return to work may result in a catastrophic fracture. See Chapter 35 for a discussion of management of horses with fractures of the proximal phalanx.

Fractures of the condyles of the McIII or the MtIII are a frequent injury, but they occur more often in 3- and 4-year-olds than in 2-year-olds. The lateral or medial condyle can be affected, and fractures of the medial condyle of the MtIII often spiral proximally. The whole fracture may not be seen on one radiographic image, and several oblique images should be obtained to determine the extent of the fracture before contemplating general anesthesia for surgical fixation. Spiral fractures present a risk during recovery from general anesthesia.

A complete, displaced condylar fracture presents little diagnostic challenge. The horse is extremely lame and resents palpation of the lateral or medial condyle. Flexion of the metacarpophalangeal/metatarsophalangeal joint invariably is associated with sharp pain, and joint capsule distention and effusion usually occur because of hemorrhage. Short, incomplete condylar fractures are more difficult to diagnose. Lameness is usually severe (grade 2 or 3 of 5) and diminishes rapidly with rest. Horses often become lame again as soon as they are returned to cantering exercise. Diagnostic analgesia localizes lameness to the metacarpophalangeal/metatarsophalangeal joint, but nothing may be seen radiologically. A flexed dorsopalmar image is vital if these lesions are to be seen adequately.³ If radiography is performed in the field, using portable equipment, then an upright flexed image that moves the PSBs proximally is useful to identify the fracture⁴ (see Figure 107-4).

If a condylar fissure is suspected, the horse should be restricted to walking and trotting exercise for 2 weeks before follow-up radiography is performed. Many horses that eventually develop full, displaced condylar fractures are described as having been bad movers before injury, and almost certainly prodromal pathological damage contributes to the cause of these fractures. See Chapter 36 for a discussion of management of horses with fractures of the McIII and the MtIII.

Pain Associated with the Tarsometatarsal Joint

Sore hocks are probably much more common in the United States than they are in the United Kingdom. TMT joint lameness can be bilateral or unilateral and often does not resolve with rest, and the response to intraarticular administration of corticosteroids varies extremely. I treat horses with triamcinolone acetonide (10 mg) at the time of intraarticular analgesia to avoid having to reenter the joint. After this therapy, many horses are sound, and lameness never returns. However, other horses require intermittent repeated medication, and others will not respond at all. The withdrawal period for racing free of medication is probably longer for triamcinolone acetonide than many other corticosteroids and can be in excess of 20 days after injections of the distal hock joints in the United Kingdom.

Horses with bilateral lameness are more difficult to diagnose. Bilateral plantar stress injuries in the distal aspect of the MtIII should be eliminated first by diagnostic analgesia because the gait of affected horses is similar. If diagnostic analgesia is negative, local analgesia of one TMT joint should be performed in the hope that an obvious lameness will become visible in the contralateral limb. Care should be taken if medicating both TMT joints to avoid a laminitis-inducing dose of corticosteroid (i.e., no more than 20 mg of triamcinolone acetonide per horse). The very prolonged detection period of depot preparations of drugs such as methylprednisolone acetate virtually rules out the use of this drug in horses racing under European medication rules.

The North American Standardbred

*James B. Mitchell, John S. Mitchell,
Paul M. Nolan, and Mike W. Ross*

DESCRIPTION OF THE SPORT

The Standardbred (STB) was developed as a racing breed by registering any horse that could trot or pace 1 mile in a set time, called the standard. An early standard was 2:30 (2 minutes, 30 seconds, 0 fifths). Early STBs were diverse because they were different types with a large genetic pool. Crossing many types resulted in a strong, rugged breed that lacked refinement of the head, ears, and bone structure. Trotters were large and coarse, whereas pacers were smaller and more refined. The breed has progressed rapidly by selective breeding in the past 4 decades. Although trotters and pacers now are bred separately, the physical appearance has become more alike, and both lines have a racy appearance similar to Thoroughbreds (TBs). Early trotters were farm or buggy horses, selected for good disposition and durability, traits that are still characteristic. Early STBs were raced several 1-mile races in the same day, called heats, a part of the sport demanding stamina and gameness.

A TB stallion, Messenger, imported from England in 1788, was prominent in the formative period of the STB. Many of his offspring had a natural inclination to trot. In 1849, a descendent of Messenger sired Hambletonian 10, the foundation sire of the STB breed. The breed developed

in the northeastern United States, where it was influenced by the Hackney and Morgan breeds and local mixed-breed horses.

The STB races at two different gaits: the trot, a diagonal two-beat gait in which the left forelimb (LF) and right hindlimb (RH) move together, and the pace, a lateral two-beat gait in which the LF and left hindlimb (LH) move together. High knee action and a lateral (left to right) nodding of the head are typical of a trotter (Figure 108-1, A). A trotter travels straight ahead (see Figure 108-1, A) (Figures 108-2, A, and 108-3), but a pacer sways from side to side while moving forward (see Figure 108-1, B).

Fifty years ago trainers had to spend several months determining at which gait a STB was more talented; some could not handle speed at either gait. As late as the 1970s and 1980s, it was not unusual for a horse to race one season at one gait and the next season at the other. A few horses raced at different gaits weekly, but today most STBs race at only one gait. Many foals pace or trot naturally. Although trotters trot while racing, they occasionally break into a pace when they are lame. Pacers often jog—the term used for trotters and pacers when trotting the slow or wrong way (clockwise) of the track at the trot—but train and race at the pace. The pace is faster than the trot. The current (2009) world record for the pace during a parimutuel race is 1:46.4 (all-age, any size track) and that for the trot is 1:49.3 on a track longer than 1 mile and 1:50.1 on a 1-mile or smaller racetrack. Many purists in the sport do not consider a world record on a racetrack longer than 1 mile to be equivalent to that obtained on a smaller racetrack because there is only one turn compared with two or more on smaller racetracks. Many pacers race near record time, but trotters do not. Trotters and pacers do not race against each other in parimutuel races. A STB racehorse must qualify for racing, meaning the horse must better or match a minimal speed before being entered into a parimutuel race. Another form of speed test is called a time

Fig. 108-1 • A, Muscle Hill, a champion 3-year-old trotting colt of 2009, is seen here with driver Brian Sears. This talented young trotter equaled the all-age trotting world record of 150.1 in his overwhelming victory in the Hambletonian, raced at the Meadowlands racetrack outside of New York City. **B**, Paul MacDonell guides Somebeachsomewhere, a champion 3-year-old pacing colt in 2008. Somebeachsomewhere equaled the all-age pacing world record with his 146.4 performance at the Red Mile in Lexington, KY. (Courtesy United States Trotting Association, Columbus, Ohio, United States.)

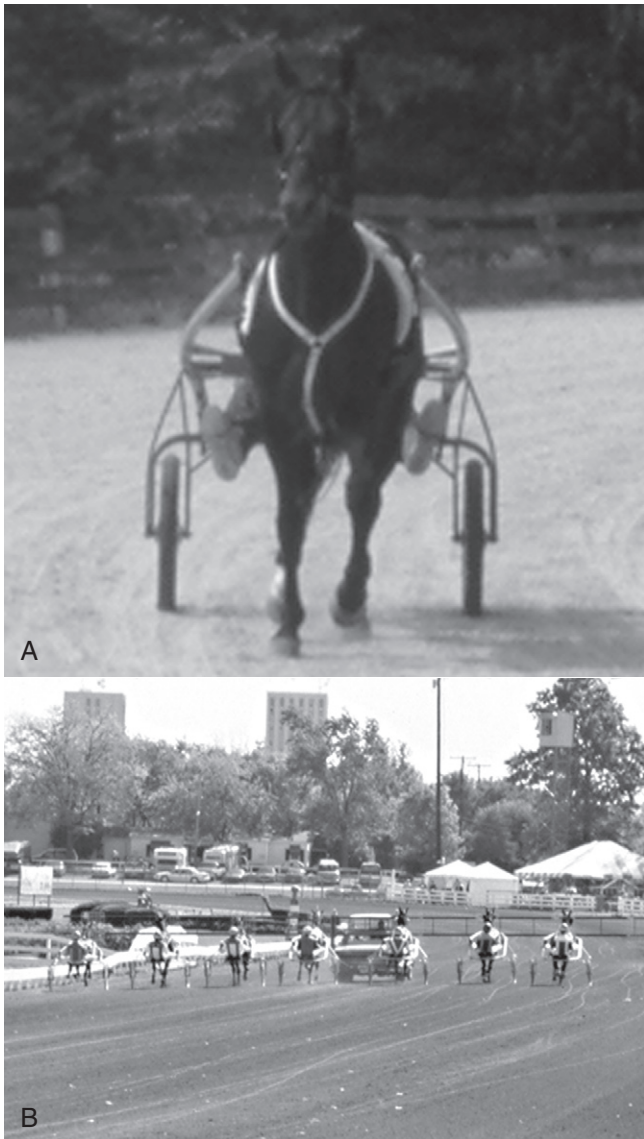

Fig. 108-2 • A, A young trotter is on the left shaft coming out of a turn on a small farm track. On this track a horse has to negotiate four turns to train 1 mile. **B,** Horses approach the start of a race at the Red Mile, Lexington, Kentucky, a track that is 1 mile long. Compared with the turn in **A**, the turn on this track is substantially larger, and horses must negotiate only two turns for a 1-mile race.

trial. At certain 1-mile-long racetracks, horses compete against a prompter, usually a TB in harness, and go as fast as possible, but the prompter cannot pass the STB. The world record for the time trial is 1:46.1 set by a pacer. Mean race times of STBs are decreasing constantly (the horses are becoming faster) because of selective breeding, changes in track surfaces and banking, popularity of 1-mile racetracks (racing is faster because horses only negotiate two turns), refinement in race bikes (sulky), and advances in veterinary care.

Early trotters were raced under saddle and then with carts and wagons, with a time under 3 minutes being noteworthy. Sulkies appeared regularly in races in the 1840s, and the 2:30 barrier fell in 1845, becoming a time standard for the era. Race times fell steadily, and in 1897 a stallion named Star Pointer paced a mile in under 2 minutes.

Fig. 108-3 • This trotter is on the left line and the right shaft in the straightaway. The horse's head is turned to the left because the driver (Rich Ringle) has to pull harder on the left rein to keep the horse going straight. The horse's hindquarters are closer to the right shaft. This combination of left line and right shaft would be consistent with left hindlimb lameness.

The first horse to trot the 2-minute mile was Lou Dillon in 1903.

North American STBs start a race behind a moveable starting gate, a vehicle carrying a barrier to keep the horses in line until the gate pulls away, at which time the horses accelerate to start the race evenly. In some countries, horses start from a standing start, a staggered standing start, or a moving start without a gait. In Europe, races are only for trotters, and top 3-year-old and older North American trotters often are sold to European buyers.

STBs in North America are divided into four classes. The first is the International trotter that races in the top competitions in North America and Europe. The second is the Grand Circuit or stakes horse that travels from track to track, racing against the top 2- and 3-year-old horses. These horses may earn more than 1 million dollars a year. The third class includes the greatest number of horses stabled at or near a parimutuel track. These horses race repeatedly at one or two different tracks and are referred to as overnight horses. Overnight horses are raced in condition races, grouping similar quality horses by earnings, age, or sex, or in claiming races, where horses are grouped by price. The fourth class, county fair racehorses, popular mostly in the northeast and midwest United States, race for small purses at county fairgrounds, often under adverse track conditions, but they provide thrills for fans and owners beyond those of races with richer purses.

Amateur STB driving and racing under saddle are hobby-type events that are increasing in popularity. STBs compete at horse shows in the roadster classes, hitched to a bike or wagon, and also as road horses under saddle. Former STB racehorses are not only popular in the Amish community, but they also can be found performing

diverse sporting activities such as low-level dressage and jumping. The Standardbred Retirement Foundation (<http://www.adoptahorse.org>) helps to find homes for former racehorses; the Harness Racing Museum and Hall of Fame (<http://www.harnessmuseum.com>) and the United States Trotting Association (<http://www.ustrotting.com>) are worthy causes and valuable sources of information about the North American STB.

TRAINING

A classically trained STB has about 9 months of schooling and training before its first race. Most horses start training in the fall at 1½ years of age and begin racing the next summer. Many states have racing programs for 2-, 3-, and 4-year-old horses and require a horse to be nominated early in life. Eligibility then is maintained by periodic payments, called stake payments, creating a large pool of money divided among the winners of elimination and final events. Although some stake races receive track or corporate purse assistance, owners who put up their own money support most races. Stake races are limited by age and sex. For example, 2-year-old trotting fillies race together. Stake payments must be made early in the spring, before talent and speed of individual horses can be confirmed, and owners, trainers, and veterinarians must decide which horses to stake. Emphasis on racing young STBs and the money necessary to maintain stakes eligibility place extreme pressure on trainers to race horses at 2 and 3 years of age. Horses often are pushed farther and faster than is reasonable, placing them at risk of stress-related bone injury, usually of subchondral bone. Many owners do not realize the difficulty of having a horse compete based on a calendar of scheduled events, expecting the horse to peak for the biggest purses, rather than on the horse's training and fitness level. The process of nominating and planning for stakes races is an art and science, and often a staking service is hired to organize periodic stake payments. Stake payments are a considerable expense, and some owners spend several hundred thousand dollars a year. Horses not nominated, those dropped from stakes programs because of injury or lack of talent, or those in which payments were missed are still eligible for overnight racing. More and more late closer and entry-only stakes are becoming available for nonstaked horses.

A STB is trained in a jog cart that is stronger, longer, and about three times as heavy as the 14-kg sulky or race bike. A young pacer is soon equipped with hobbles, which are leather or plastic straps encircling the ipsilateral forelimbs and hindlimbs, to keep legs moving in unison (see Figure 108-1, B). A horse capable of sustaining a pace without hobbles is called a free-legged pacer, but few race without hobbles. Hobbles can cause areas of hair loss on the cranial aspect of the forearm and the caudal aspect of the crus called hobble burns, which are typical marks of a pacer. Trotting hobbles, which are straps encircling both forelimbs that run through a pulley underneath the horse, have become popular and are being used on more and more trotters in recent years, even those competing in top stakes races. Trotting hobbles may stabilize the trotting gait at speed. Some in the industry frown on the use of these equipment additives, claiming they may give an unfair advantage and historically have not been used.

Equipment is important in understanding gait and lameness. Head poles, boots, brace bandages, gaiting straps, and gaiting poles are used to improve gait and performance, as well as to assist in steering the horse at racing speed. A head pole keeps the horse from turning the head and neck to the opposite side. A horse with right forelimb (RF) lameness usually bears left, called bearing in or on the right line, because the driver pulls on the right line, causing the horse to turn the head to the right. This horse would wear a left head pole. Gaiting straps and poles run alongside the horse and attach to the cart beside the driver's seat and are used to keep the horse straight. Horses with unilateral hindlimb lameness often carry the hind-quarters near the contralateral shaft, called being on the shaft. A horse with RH lameness goes on the left shaft and requires a left gaiting pole or strap. Boots are applied to minimize interference injury. Some horses chronically interfere, whereas interference in others is accidental. Soft brace bandages are used for protection and to widen the hindlimb gait.

Training the Young Standardbred

Yearling STBs are introduced to the harness and bridle in the stall and then are line driven at a walk for several days before being hitched and jogged on the track. Once the horses can go to the track with a single driver, trainer, or groom, they are jogged 1 to 2 miles each morning, usually in a clockwise direction (wrong way) first. Young STBs are encouraged to jog at the intended gait as soon as possible. STBs are usually jogged 6 days a week at slow speed. This is usually natural for trotters, but many pacers need hobbles or special shoeing. Weight usually is added to hind shoes of pacers, especially to the outside web, whereas the front feet may be left unshod. In trotters, weight is added to the front shoes. Shoeing and equipment changes begin early to produce the best gait possible.

Jogging is increased 1 mile every few weeks, up to 4 to 5 miles daily. Horses are taught to jog both ways of the track. Most young horses are jogged in groups, so horses overcome fear of traveling in close proximity. In large stables, horses are trained in sets of three to five to teach passing and racing in tight quarters and to simulate racing. In addition to jogging, horses are trained fast every 3 to 4 days initially, but later twice weekly, going counterclockwise (the *race or right* way on the track). Horses are trained 2 and sometimes 3 fast miles on training days but usually go back to the barn for a breather (to blow out) between fast miles (trips). STBs develop tremendous stamina compared with TBs, but fatigue and strain cycles predispose them to stress-related injury of the subchondral bone, not commonly of cortical bone unlike TBs. When the fastest miles approach racing speed, young horses are ready for baby or schooling races to learn how to leave the starting gait. It is interesting that most STBs are trained, schooled, and qualified in the morning daylight and then make the first parimutuel start at night under the lights.

Retraining a Racehorse

The classic retraining approach involves jogging 2 to 5 miles a day and additional training one to two times a week. A fast workout usually consists of two to three fast trips, which are simulated race miles taken at increasing speed. Horses usually are allowed to blow out between

trips. Some are given double headers, which are two 1-mile workouts without returning to the barn, but they walk or jog slowly between trips. A break is when a horse leaves the expected gait and breaks into a gallop. Many training miles are given to obtain maximum physical fitness and to condition the horse to travel at speed without breaking. Many training miles are considered necessary to evaluate and adjust equipment and shoeing. Diagnostic analgesia can be performed between trips.

Alternative training methods produce good results and are customized to the disposition and physical condition of the horse. Trainers now use interval training, straight tracks, inclines and hills, swimming, towing behind a vehicle, and mechanical walkers or joggers. With relocation of European trainers to North America, more alternative techniques have been introduced, including riding trotters between races.

Once racing, work is customized to each horse's needs. Hard training using the classic training method consists of one race and two training trips per week, but in this system horses are under considerable stress. Now that the breed is refined and heat races are fewer, racing horses are given much less training between races, and fast work may not be given at all. Reducing exercise intensity between races is important in managing STBs with chronic lameness.

LAMENESS AND POOR RACING PERFORMANCE

Lameness is the leading cause of poor performance and a major cause of STBs making breaks. Some overnight and stakes horses are chronically lame but race weekly, although lame horses race slower, and horses drop in class as lameness progresses. The major effect of lameness is seen during the last quarter of the race, called the last quarter time. Lower-class horses usually have a fast opening quarter but slow last quarter time, whereas open and stakes horses have fast quarter times anytime during the race. Evaluation of last quarter time is useful to determine cause and severity of poor race performance. Lameness often costs a horse 1 to 2 seconds in last quarter race time, equating to 5 to 10 horse lengths. For example, a horse that normally paces the last quarter in 27.1 seconds but for the last few starts has been coming home in 28.4 to 29.2 seconds is probably lame, although concomitant respiratory and metabolic problems cannot be overlooked.

TRACK SURFACE AND LAMENESS

STBs usually race around an oval track, $\frac{1}{2}$ to 1 mile in circumference; a 1-mile track is most common. Races are usually 1 mile, but a few are $\frac{5}{8}$ -mile sprints to 2-mile races. The track surface is a crushed rock base, covered with a packed, sandy soil and a thin sand or stone dust surface. STB racing requires a much firmer track surface than galloping horses. Sulky tires are more efficient if rolling over a firm smooth surface, and the STB gaits require a firmer and smoother surface than does the gallop. Track surfaces have become firmer because year-round racing requires a surface suitable for racing in rain and subfreezing temperatures. Hard tracks with loose surfaces require horses to wear shoes with added grabs and welded-on spots of borium to avoid slipping. Excessive slipping or overzealous use of shoes with additives predisposes horses to lameness. A soft

or deep surface can predispose horses to tendonitis and suspensory desmitis. Hard tracks with a covering of loose stone dust are slippery and may predispose horses to carpal synovitis, bruised soles, and muscle soreness. Racetracks get soft and sticky with small amounts of rain and hard and unyielding with heavy rainfall that may wash the top surface into the infield. Recently, a three-dimensional dynamometric horseshoe was used to measure acceleration and other forces on the front hoof of French trotters performing at high speed on two different track surfaces, all-weather waxed and crushed sand track surfaces.^{1,2} Hoof deceleration was significantly less, and there was a 50% attenuation of shock when horses performed on the waxed surface, suggesting this surface had better shock-absorbing qualities compared with a crushed sand surface.¹ The amplitude of the maximal longitudinal braking force was significantly lower and occurred 6% later in the stance phase. The magnitude of the ground reaction force at impact was lower on the waxed track compared with the crushed sand track surface.² The attenuation of loading rate, amplitude of horizontal braking, and shock at impact on waxed surfaces suggested that there is likely a reduction in stress in the distal aspect of the forelimb, results that may be important in training normal horses or rehabilitating STBs with infirmities.²

TRACK SIZE AND LAMENESS

Track size has substantial implications in the development and expression of lameness. Tracks are 1 mile, $\frac{7}{8}$ mile, $\frac{5}{8}$ mile, and $\frac{1}{2}$ mile, and in general race times are lower (faster) on large tracks. Because most STB races are 1 mile, track size determines the number of turns during the race. During a race on a $\frac{1}{2}$ -mile track, a STB must negotiate four turns. Turns on smaller racetracks are much tighter than those on larger tracks (see Figure 108-2). There is a single racetrack larger than a 1-mile oval, Colonial Downs in Virginia, at which a short race meet is held each year; on this track, races involve negotiating a single turn. Horses racing with mild chronic lameness are less likely to sustain speeds necessary to be competitive on larger tracks, so they may race on smaller tracks; however, if lameness is worse in the turns, the horse may be less competitive on small tracks and better suited for a 1-mile track. If lameness is worse in the straightaway, the horse may be best suited for a small track. This is particularly important when lameness worsens as the race goes on because large tracks have a long straightaway at the end.

During counterclockwise racing, right-sided lameness conditions exert more influence, even though the LF and LH are on the inside. Horses with left-sided lameness can race successfully on small tracks and apparently negotiate turns well. However, those with right-sided lameness cannot trot or pace the turns well, most likely from the effect of centripetal and compressive forces. Ideally, all racehorses should be sound, but many horses can race successfully with mild infirmity. Horses with substantial lameness should be treated or rested until the condition improves.

CONFORMATION

Forelimb and hindlimb faults lead to lameness and interference. Severity often depends on gait. A trotter should be

as long from front to back as it is tall. Trotters are passing gaited if hind feet land outside the front feet, and in-line gaited if hind feet land in plane with the front feet. Wide hindlimb gait is advantageous because it allows a passing gait. Trotters can be mildly to moderately toed out in front without substantial interference problems, but they should not be toed in because winging out leads to interference and lateral suspensory branch desmitis. Pacers can be wide and mildly toed in but not toed out because this fault predisposes the horse to hitting the knees. A club foot is less well tolerated by a STB than a TB and usually results in foot lameness. Low, underslung heels and long toes are acquired by attempts to increase stride length or to decrease interference. Back at the knee is undesirable and leads directly to carpal lameness in a trotter, but it is better tolerated by a pacer. Offset (bench) knee is a major fault, and although horses may race successfully, lameness of the carpus and metacarpal region often develops. Mild carpus valgus is tolerated by pacers but can lead to lameness of the carpus and metacarpal region. Pacers that are tied in behind the knee are at risk of developing superficial digital flexor tendonitis, but surprisingly trotters are not. Short, straight pasterns and short backs are undesirable.

A serious hindlimb fault leading directly to moderate to severe lameness is sickle-hocked conformation (see Chapters 4 and 78). Mild sickle-hocked conformation typified many early pacers and is desired by some trainers. Sickle-hocked trotters are fast but develop curb and osteoarthritis (OA) of the distal hock joints, particularly severe in the dorsal aspect, and are chronically unsound. Sickle-hocked conformation predisposes all STBs to the development of slab fractures of the third and central tarsal bones. Straight hindlimb conformation is unusual but is a severe fault, leading to metatarsophalangeal and stifle joint lameness and suspensory desmitis. In horses with straight hindlimb conformation, excessive extension of the metatarsophalangeal joint occurs. Long, sloping pasterns also predispose horses to fetlock hyperextension, but a primary metatarsophalangeal joint weakness is seen in some trotters with normal pastern lengths, in which the base of the proximal sesamoid bones (PSBs) is level with the middle of the proximal phalanx. Abnormal elasticity or loss of support from the suspensory apparatus predisposes horses to run-down injury and suspensory desmitis. Run-down injury is more commonly seen in the hindlimbs. Cow-hocked conformation is prevalent in trotters but is not problematic unless severe. In-at-the-hock conformation predisposes horses to OA of the distal hock joints, curb, and medial splint bone disease. Base-wide and base-narrow conformational faults, if severe, can lead directly to interference and lameness.

DISTRIBUTION OF LAMENESS

STB racehorses have a higher percentage of hindlimb lameness than TBs. The STB trains and races using a two-beat gait: two limbs bear weight simultaneously. Load is shared almost equally between forelimbs and hindlimbs. The caudal location of the cart and driver (load) and the addition of the overcheck apparatus shift the center of balance caudally, increasing hindlimb lameness (see Figures 2-2 and 2-3). The distribution of forelimb to hindlimb lameness is approximately 55% to 45%.

LAMENESS IN THE YOUNG STANDARD BRED

The top 10 list (see page 1024) contains those conditions seen in STB racehorses of all ages when grouped together, but unraced 2- and early 3-year-olds develop a subset of lameness conditions. Osteochondrosis (see Chapters 54 and 56), splint exostoses (splints), and curbs are common. Forelimb splints are usually medial but can occur laterally. Hindlimb splints are almost always medial and are more common in trotters. Splints can cause primary lameness or be secondary to carpal lameness, especially if the exostosis is proximal. Forelimb splints develop when the limb is carried or lands abnormally. Young horses develop splints from difficulty learning the racing gait and by making breaks. While breaking, pacers often hit themselves because galloping in hobbles is difficult. Curb is common in young pacers and may be recognized while horses are jogging, before training begins (see Chapter 78).

Carpal lameness is common in young horses. The middle carpal joint is the most common site, but synovitis can occur in the antebrachio-carpal joint. Carpal lameness is caused by early subchondral stress-related bone injury of the third carpal bone and is particularly common in trotters. Paddock turn out for 30 days is recommended. Middle carpal joint lameness must be differentiated from proximal suspensory desmitis (PSD). The thought once was that the distal radial physis was a source of occult carpal region lameness, but diagnosis was never confirmed. Physeal pain is a rare diagnosis today, but some veterinarians believe such pain is a possible source of so-called colt soreness.

Bucked shins are rare but do occur in 2-year-old pacers in July and August. Most bucked shins occur in the forelimbs. Genuine bucked shins rarely occur in trotters, but interference trauma of the dorsal cortex of the third metatarsal bone (MtIII) is common.

Distal hock joint pain is a common cause of acute unilateral lameness, but if pain is bilateral, overt lameness may not be present. Horses appear stiff and sore when starting out and warm out of lameness. Gait abnormalities and repeated breaking may cause distal hock joint pain. Lameness may be difficult to abolish completely with intra-articular analgesia because pain is multifactorial, arising from periarticular soft tissues and secondary gluteal myositis and trochanteric bursitis. Horses should be rested for 1 week and given nonsteroidal antiinflammatory drugs (NSAIDs) such as phenylbutazone (2.2 to 4.4 mg/kg orally [PO] twice daily). Intraarticular injections are avoided if possible, but treatment of the tarsometatarsal (TMT) joint with hyaluronan alone, or in combination with corticosteroids, often resolves residual lameness. Using a less aggressive training schedule for 20 to 30 days is recommended. Shoeing should be evaluated, and grabs and calks should be removed or minimized.

Interference injuries are common and plague many STBs throughout the racing career. Trotters interfere primarily by striking the toe of the ipsilateral front foot to the shin, pastern, or coronary band regions of the hindlimb (see Chapter 7 and Figure 7-2). Interference from a front foot striking the medial aspect of the contralateral forelimb (cross-firing) occurs occasionally in trotters but is a major form of interference injury in pacers. Injury to second (McII) and third metacarpal (McIII) bones, PSBs, carpus, heel, and hoof wall causes bruising and hematoma

formation. Contusions can lead to soreness or frank lameness and can cause an altered gait. A trotter attempting to avoid striking the LH shin shortens the cranial phase of the stride, causing what appears to be a pelvic hike, mimicking LH lameness. Deliberate hiking can alter load distribution, causing compensatory lameness in the RH and RF. Local trauma is treated, and changes in equipment and shoeing, such as applying brace bandages and boots, are performed. A brief (5 to 7 days) reduction in exercise intensity is useful to allow a young horse to gain confidence in the corrected gait.

Young horses with poor gait should be examined carefully for neurological disease. Equine protozoal myelitis (EPM) is endemic in STBs and can be a real cause of gait deficits or a catchall diagnosis (see Chapter 11).

CLINICAL HISTORY

Clinical history is critical for lameness diagnosis and to put lameness into context with other causes of poor racing performance. The attending veterinarian with an established relationship with the horse may know the horse's history. A trainer often refers to mild lameness by saying, "The horse is just sore, Doc," or "The horse is off when jogging, but throws it away when going the right way." STBs have unusual resiliency and race rather well with chronic lameness, but lameness does not resolve with speed. Owners do not understand this concept. Signs of lameness become less visually apparent when horses go fast. Because STBs often race with numerous compensatory lameness problems, one must be open to the possibility that current lameness is not worsening of an existing problem but is an entirely new one.

A good starting place is to determine the chief complaint from the person(s) closest to the horse, usually the groom and trainer. What differs now from the horse's normal activity, gait, or performance? Has a change in training or racing schedule occurred? Has there been a change in track surface? A horse noticed to be stiff and sore up front when walking to the track may be foot sore the day after the horse raced on a hard track. Have any equipment or shoeing changes been made? Additions of head poles, gaiting straps, and boots point to high-speed lameness and gait abnormalities. Shoeing changes, such as adding or removing bar shoes, are important because horses used to wearing bar shoes may have sore feet if bars are removed. Metacarpophalangeal joint lameness may be worse if bars are added. Stress-related bone injury of the metatarsophalangeal joint is seen soon after aluminum shoes with toe grabs are applied. Is the horse receiving any current medication, and when was the horse last examined? What treatments, if any, were given? Although an acute injury or worsening of chronic OA can cause acute synovitis, inflammatory and infectious arthritis can develop days to weeks after intraarticular injections, particularly if corticosteroids were used, because these drugs can suppress signs of inflammation and infection for weeks. Infectious arthritis is common 14 to 21 days after intraarticular injection, but often owners and trainers are incredulous because recent injections were not performed. What have the trainer and groom done recently to solve or treat the problem? Topical therapy may reduce or worsen inflammation and mask or augment clinical signs. Skin soreness after

application of paints and blisters can cause a false-positive response to deep palpation.

Is the horse a trotter or a pacer? This information is critical. The usual distribution of pacers to trotters is about 3:1. Interference problems are different between gaits. Trotters often develop contralateral or diagonal compensatory lameness, whereas pacers most often develop ipsilateral compensatory lameness. A pacer with a left carpal lameness often develops LH compensatory lameness, but a trotter is more likely to develop compensatory lameness in the RH. Although this distribution of compensatory lameness is common when examining horses trotting in hand, load distribution and interference issues may complicate and change visual appearance of where primary lameness originates when a STB is pulling a cart on the track and on which gait the horse is performing. The distribution of lameness differs between gaits. Fractures of the proximal phalanx and the McIII and the MtIII and superficial digital flexor tendonitis are less common in trotters. Trotters with stifle lameness, specifically OA of the medial femorotibial joint, can cope better than pacers. Race times are different. Prognosis for certain problems such as osteochondral fragments of third carpal and radial carpal bones is worse in trotters. Pacers are more likely than trotters to start a race and to have five starts before and after surgical removal of osteochondral fragments of the carpus.³ Osteochondrosis is common in certain bloodlines of trotters and pacers.

Is the condition worse at the trot or pace? Trotters and many pacers trot while jogging the wrong way but assume the intended gait when turned the right way. Most forelimb lameness conditions are less obvious at the pace, but hindlimb lameness differs. In general, STBs with stifle lameness are worse at the pace than the trot. If trainers comment that the horse is worse at the pace than at the trot, the veterinarian should suspect stifle lameness until proved otherwise. Pacers wear hobbles, but trotting hobbles are often used in trotters making breaks.

Is lameness different depending on what direction the horse moves? Problems on the right side are worse going the right way of the track (counterclockwise). Horses with medial foot and carpal lameness may show signs in the turns, especially entering the turning radius going the right way, but not when jogging.

What is the horse's last quarter time? Although high-speed lameness can cause a 1- to 2-second decrease in last quarter time, horses with mechanical upper airway disease and rhabdomyolysis have a 2- to 4-second reduction, and those with severe lameness or atrial fibrillation have a 5- to 10-second reduction in last quarter time.

Is the horse on a line? This is one of the most important pieces of information to obtain. Trainers sometimes dismiss young horses being mildly on the line because nervous and inexperienced horses may change directions suddenly, but in reality most of these abnormal movements are caused by lameness. During counterclockwise racing of a horse on the right line, the driver has to increase the tension (pull harder) on the right rein to keep the horse straight and prevent it from bearing toward the infield. Just the opposite occurs when horses are on the left line (see [Figure 108-3](#)). Because of bit pressure, when a horse is on the left line, it turns or cocks the head to the left, toward the inside rail, and vice versa. If history is unclear, the veterinarian should watch the horse on the track and observe head

position. Because most horses bear away from pain, a horse on the right line is most often lame on the right side, but exceptions occur. A common finding is metacarpophalangeal effusion and a positive response to lower limb flexion. The trainer states, "The horse was on the left line when finishing the mile, but is usually on the right line especially in the turns." Primary lameness may be in the right carpus, but chronic RF lameness has caused compensatory overloading and lameness of the left metacarpophalangeal joint, and both areas should be evaluated and potentially treated. Most horses on a line from forelimb lameness have foot or carpal lameness. However, problems located medially, such as medial sole bruising, quarter cracks, or carpal lameness, paradoxically can cause a horse to be on the contralateral line. Horses may lose power in the affected limbs and drift at speed toward the lame side. Therefore a horse with a medial LF quarter crack could be on the right line, whereas those with a right carpal lameness could be on the left line. All limbs should be examined because not all horses read the book. "If a horse is on the left line, think right hind," one old saying goes, and rarely a horse with RH bruised or cracked heels will be on the left line.⁴

Horses on a line without overt signs of lameness are among the most difficult lameness mysteries to solve. Because compensatory lameness problems may be numerous in a horse in which primary lameness cannot be ascribed, deciding on which limb to begin diagnostic analgesia is a dilemma. Most horses need to be examined at speed after blocking, a time-consuming and frustrating process. In many horses on a line, obscure sources of pain such as subchondral bone can be difficult to identify, and horses often are referred for scintigraphic examination. Most horses chronically on a line have had many intraarticular or other injections, and trainers will state, "We've done his knees, hocks, stifles, and feet and nothing helped." Often forgotten are the metatarsophalangeal joints. In many horses numerous sites of pain must be managed simultaneously rather than sequentially. Recommending numerous intraarticular and regional injections, a shoeing change, and a change in exercise intensity in a horse that is on a line is not unusual.

Is the horse on a shaft? A horse with RH lameness drifts to the left (see [Figure 108-2](#)) and positions the hindquarters closer to the left shaft of the sulky and is thus on the left shaft; the reverse is true with LH lameness (see [Figure 108-3](#)). Not all hindlimb lameness problems cause horses to be on a shaft. Horses with OA of the medial femorotibial joint may not be on a shaft, but those with distal hock joint pain will be. A horse may be falsely on a shaft if it is hard on a line and the driver pulls hard to keep the horse straight, compelling the horse to twist its entire body, positioning the hindquarters close to one shaft to maintain balance.

Is the horse worse in the turns or on the straightaway? Although nothing is pathognomonic, a few findings are consistent. Horses with front foot lameness, splints, and curbs get worse as the mile progresses and so appear worse on the final straightaway. Horses with distal hock joint pain appear to be worse when going into or coming out of a turn but usually can pace and trot the turns successfully. Horses with carpal, metatarsophalangeal, and stifle joint lameness are worse in the turns. If a horse gets rough in the first turn just after leaving the gate, a medial

RF problem such as a splint or carpal lameness should be suspected.

On what size track does the horse race? The relationship of track size to expression of lameness and the differences between left- and right-sided lameness problems were discussed (see page 1017).

Is the horse making breaks? Unsound trotters often break stride and gallop but occasionally break into a pace. Lame trotters may pace when trotted in hand. Because high-speed lameness often causes pacers to gallop and trotters to pace or gallop, it seems that the gallop may be the easiest gait that a lame horse can maintain at speed. The most difficult gait to maintain at speed is the trot, followed by the pace, and lastly the gallop (MWR). Interference injury causes breaks, and current shoeing or recent changes should be evaluated. A different way to hang up a horse, meaning how to shoe and equip it, may be all that is needed.

The veterinarian must be current on all medication rules in the racing jurisdiction because changes, such as recent (2009) modifications of allowable blood levels of corticosteroids, may impact management strategy.

LAMENESS EXAMINATION

The lameness examination can be divided into three stages: palpation, observation while moving on a lead shank, and observation under harness. The veterinarian should avoid narrowing the examination to the area suspected by the groom and trainer but should first stand back and observe the horse and watch the horse moving around and coming out of the stall. Subtle neurological signs may be apparent. Asymmetry, such as muscle atrophy, may point toward chronic lameness or neurological disease.

Palpation

Careful palpation is the art of diagnosis in the racehorse but often is sacrificed because palpation is time consuming. Palpation is critical in STBs because of numerous compensatory lameness problems. The veterinarian needs to be able to "read" the horse to make a diagnosis. A successful lameness detective respects what the horse is trying to say. The veterinarian should move over the entire horse with a light touch to see whether a withdrawal response is elicited. A light touch along the neck and gluteal regions may elicit pain from secondary muscle soreness or painful previous intramuscular injection sites. Horses often exhibit a withdrawal response when a limb is first picked up, indicating a problem even before the specific region is manipulated. Horses may exhibit false-positive responses in areas that have been recently painted, blistered, or freeze fired. Once horses have been freeze fired for splints and curbs, many trainers assume the problem has been solved and are incredulous if the veterinarian suggests the area is still the source of pain. Cryotherapy is not a panacea and may have to be repeated, or another form of management may be needed (see Chapters 78 and 89).

Palpation should be done in a quiet place, before the horse is trotted in hand, so that all potential lameness problems are detected. Careful and detailed examination of the front feet should be performed. Hoof tester examination is critical, but most horses show a painful response for 1 to 2 days after racing, particularly if the track was hard.

Effusion of the distal interphalangeal (DIP) joint capsule often accompanies early OA and sore feet. Shoes on the front and back feet should be evaluated critically for wear, type, weight, and the presence of additives. The proximal, dorsal aspect of the proximal phalanx should be palpated for pain associated with midsagittal fractures of the proximal phalanx. Palpation findings in the metacarpophalangeal and metatarsophalangeal joints often do not correlate well with degree of lameness, response to diagnostic analgesia, and results of scintigraphic examination. The presence of mild warmth (heat) on palpation, a subtle clinical finding, is an important observation for detection of subchondral bone pain in the distal aspect of the McIII or the MtIII. Pain on palpation of the PSBs may indicate sesamoiditis. Normally a horse responds little to compression of the suspensory ligament (SL), deep digital flexor tendon (DDFT), and superficial digital flexor tendon (SDFT). Pain is often the first sign of desmitis or tendonitis. Chronic enlargement of the SL and SDFT is common in lower-class horses, and although a horse may not react to palpation, it may have associated high-speed lameness. Splint exostoses are most painful after training or racing but may be nonpainful several days later. Standing and flexed subcarpal palpation may reveal pain associated with PSD, longitudinal and avulsion fractures of the McIII, proximal superficial digital flexor tendonitis, and a dorsal medial articular fracture of the McIII.

No palpable abnormalities may be associated with carpal lameness. The veterinarian should carefully assess for warmth and compare the limb with the contralateral limb. If the horse has been clipped for the application of a paint or blister, the affected area will feel warm compared with the surrounding unclipped skin. Effusion occurs in 2-year-old horses early in training, but it often is minimal in horses with subchondral bone pain. The antebrachio-carpal joint is rarely a site of carpal lameness in older racehorses, but in young horses, especially trotters, effusion may occur. The medial aspect of the carpus and the distal aspect of the antebrachium are common sites for interference injury. Carpal tenosynovitis is unusual to rare, but occasionally hyperextension injury and hemorrhage occur. Rarely, almost always in trotters, desmitis of the accessory ligament of the SDFT occurs, associated with carpal tenosynovitis. Pacers develop hobble burns and cellulitis in the proximal aspect of the antebrachium. Elbow and shoulder joint lameness is rare, but horses may exhibit pain when the biceps brachii, intertubercular bursa, and other muscles are palpated or the shoulder joint is flexed, from muscle soreness secondary to primary carpal lameness. The neck, back, and rump regions should be palpated for symmetry and muscle soreness. Young horses will occasionally manifest sore withers from an improperly fitted harness. Because intramuscular injections of counterirritant and antiinflammatory solutions are common in STBs, careful palpation is necessary to discover deep abscesses causing pain, lameness, and fever. Disease of the thoracic dorsal spinous processes is rare. In a 16-year period, only one of nearly 2400 STBs undergoing scintigraphic examination had increased radiopharmaceutical uptake (IRU) in the dorsal spinous processes or the intervertebral synovial joints, and no bony abnormalities were found in the pelvis.⁵

Secondary muscle soreness of the gluteal region is a common problem, and the diagnosis of trochanteric

bursitis often is made based on a painful response to compression. Trochanteric bursitis (whorl bone disease) may be overdiagnosed and difficult to authenticate, but injections often improve hindlimb gait and performance (see Chapter 47). Rhabdomyolysis also can cause pain on palpation of the rump region. Young horses with loose stifles often knuckle behind, but palpation is often negative. Pain associated with the medial aspect of the stifle may be present, but abnormalities when manipulating the patella are absent. Femoropatellar effusion in young horses can signal osteochondrosis. The medial femorotibial joint capsule should be palpated because OA is the most important cause of lameness of the stifle. The crus is a rare site of pain. Hobble burns on the caudal aspect can cause soreness in young pacers.

The tarsocrural joint is the most common site for osteochondrosis, and effusion in young horses should prompt radiographic examination. Periarticular pain in the distal aspect of the tarsus and proximal metatarsal region often accompanies distal hock joint pain. The Churchill test is done routinely, but in addition to those with distal hock joint pain, STBs often respond positively with other common distal limb lameness. Bony enlargement (bone spavin) is rare. Plantar soft tissue swelling and pain associated with curb is a common cause of lameness (see Chapter 78). The plantar metatarsal region commonly is overlooked, but it should be palpated carefully for the presence of suspensory desmitis. Signs of inflammation may be difficult to detect because the SL is enclosed within the bony confines of the metatarsal bones. The first evidence of suspensory desmitis is mild enlargement and pain of the suspensory body in the midmetatarsal region. Compression of the splint bones puts indirect pressure on the SL and explains why the Churchill test is nonspecific. The dorsal aspect of the MtIII is a common site for interference injury in trotters. Palpation of the fetlock region is critical because the region is an important source of lameness, but often no localizing clinical signs are apparent. Mild warmth may signal the presence of subchondral bone injury. Pain from interference injury should be differentiated from that associated with midsagittal and dorsal plane fracture of the proximal phalanx. The hind foot is an unusual source of lameness, but fractures of the distal phalanx, bruising, navicular disease, and OA of the DIP joint are diagnosed occasionally. STBs normally respond positively to hoof testers placed across the heel.

Movement

The horse should be examined at a walk and trot in hand. The pace is a forgiving gait, and head and neck nod and pelvic hike can be difficult to see. Evaluating lameness in pacers is easier while they are trotting, but correlation between lameness seen in hand and during pacing at high speed is questionable. Forelimb lameness is less obvious at the pace. Degree of pelvic hike is comparable at the pace and trot. Baseline lameness should be determined before the harness is applied because horses that are fracture lame should not be taken to the track, and a good correlation exists between lameness seen in hand and in harness in horses with obvious lameness. The ability to trot horses in hand at the racetrack may be limited because of too much activity, lack of room, and often poor or slippery surfaces. Flexion tests are performed but lack specificity. The carpal

flexion test is the most reliable and specific of all flexion tests. Direct compression of a painful splint, the proximal aspect of a SL, and a curb followed by trotting is useful. Subtle hindlimb lameness is best evaluated in harness because little correlation may exist with lameness seen in hand. Pulling a cart and different surface likely explain this observation. Subtle (less than grade 1 of 5) hindlimb lameness at the trot in hand should be taken with a grain of salt. Observation on the track puts lameness into perspective and allows evaluation of compensatory lameness. Although there may be a lack of correlation between lameness seen in hand and that observed on the track or at speed, any lameness condition may be an important contributor to poor performance. Lameness is most pronounced when horses are jogged slowly and is much less obvious with speed. High-speed lameness is evaluated by communication with the trainer and by resolving signs such as being on a line by using diagnostic analgesia.

DIAGNOSTIC ANALGESIA

Diagnostic analgesia is essential to pinpoint lameness, but trainers and owners often prefer treatment of a suspected area rather than lengthy investigation. With weekly racing, no time may be available for blocking because levels of local anesthetic solution will be detectable. Diagnosis often is made based on response to treatment. Many common lameness conditions involve subchondral stress-related bone injury, and often horses can be blocked sound but do not improve with intraarticular treatment. Perineural analgesia is more effective than intraarticular analgesia for diagnosing subchondral bone pain.

Controlling as many variables as possible is important when observing STBs in harness. The same gait, equipment, driver, approximate speed, and track direction should be used. Sometimes horses exhibit lameness when driven by the groom but not the trainer because trainers expect a higher level of performance and often carry a whip. A false-positive response occurs when a horse exhibits lameness at the pace but after diagnostic analgesia returns to the track without hobbles equipment and trots soundly. The diagnostic analgesia procedure should be the only variable. STBs often warm out of lameness and should be evaluated immediately when starting out after each block. Overzealous use of a twitch and rough handling may compromise evaluation, and administration of drugs can add another variable. If horses are observed in harness after diagnostic analgesia, the person driving the horse should be instructed to return the horse to the stable as soon as improvement is recognized because training a horse after blocking risks further injury.

Complete description of blocking techniques is found in Chapter 10. A few points about diagnostic analgesia in the STB must be kept in mind. Palmar or plantar digital analgesia desensitizes most of the foot. Horses with metacarpophalangeal or metatarsophalangeal joint lameness can be sound after palmar or plantar digital analgesia, particularly those with midsagittal fracture of the proximal phalanx.⁶ Palmar nerve blocks at the level of the PSBs are avoided because inadvertent analgesia of fetlock pain can be misinterpreted as lameness of the foot or pastern. Individual carpal joints should be blocked separately, and differentiation between carpal and proximal metacarpal

region lameness is necessary. The median and ulnar nerve block is underused.

A low plantar block must be done routinely, or many lameness conditions will be diagnosed erroneously as high up. The fetlock region is a major source of hindlimb lameness. Although subchondral bone pain of the distal aspect of the MtIII (McIII) can be abolished using intraarticular analgesia of the fetlock joint, most consistently pain is abolished using perineural analgesia. A modification of the low plantar technique, blocking only the lateral plantar metatarsal nerve, can be completed and the horse evaluated. If lameness abates, then pain associated with the lateral aspect of the fetlock joint is diagnosed; however, if no response is seen sequentially, the medial plantar metatarsal nerve, then the medial and lateral plantar nerves must be blocked. The high plantar block is often overlooked, but PSD cannot be substantiated without it. The centrodistal (CD) joint is difficult to enter but should be blocked separately from the tarsometatarsal (TMT) joint because communication occurs in only 8% to 39% of horses. The medial femorotibial joint should be blocked separately from the femoropatellar joint, even though they communicate in a high percentage of horses.

IMAGING CONSIDERATIONS

Radiography

Routine radiographic examination of STBs does not differ from that of other sports horses. However, a few specific images should be kept in mind. Down-angled oblique (dorsal 60° proximal 45° lateral-palmarodistal medial oblique and dorsal 60° proximal 45° medial-palmarodistal lateral oblique) and horizontal oblique (dorsolateral-palmaromedial oblique [DL-PaMO] and dorsomedial-palmarolateral oblique) images should be obtained to evaluate the DIP joint and palmar processes of the distal phalanx. The tangential (palmaroproximal-palmarodistal oblique) image of the navicular bone is less valuable in the STB than in other older sports horses. To evaluate the distal aspect of the McIII (or MtIII) for subchondral stress-related bone injury and the space between the proximal palmar (or plantar) aspect of the proximal phalanx and the base of the PSBs for the presence of fragments, down-angled oblique (dorsal 30° proximal 45° lateral-palmarodistal medial oblique and dorsal 30° proximal 45° medial-palmarodistal lateral oblique) images should be obtained (see Chapter 42). The most important images of the carpus are the DL-PaMO image and the tangential (skyline) image of the distal row of carpal bones. In STBs it is essential to have a well-exposed and well-positioned skyline image to evaluate the third carpal bone for increased radiopacity, radiolucency, and osteochondral fragments (see Chapter 38). Radiological changes of OA of the CD and TMT joints and slab fractures of the third tarsal bone are seen best on the lateromedial and dorsomedial-plantarolateral oblique (DM-PILO) images. A common misconception is that changes associated with bone spavin occur medially but not in young STBs. The DM-PILO image is essential in evaluating the tarsocrural joint for osteochondrosis fragments because two common locations—the cranial aspect of the intermediate ridge of the tibia and the lateral trochlear ridge of the talus—are evaluated best using this image. The caudocranial image is essential when evaluating the

medial femorotibial joint for narrowing, osteophytes, and subchondral bone cysts. Inadequate exposure and positioning often result in images that cannot be interpreted.

Digital and computed radiography are useful in evaluating stress-related bone injury of subchondral bone and incomplete fractures. Computed tomography is useful to evaluate subchondral bone and fracture configuration. Magnetic resonance imaging is useful to evaluate subchondral bone and soft tissues of the distal aspect of the limb, but scintigraphic examination is still used routinely for investigation of high-speed lameness and poor performance and continues to have great value in lameness diagnosis in STBs.

Ultrasonographic Examination

Suspensory desmitis, superficial digital flexor tendonitis, curb, and desmitis of the distal sesamoidean ligaments are common in the STB, and ultrasonographic examination is essential for diagnosis and assessing prognosis (see Chapter 16).

Scintigraphic Examination

Referral for scintigraphic examination is common, and horses with poor performance often have numerous areas of IRU, indicating high-speed lameness is a part of the problem. Common areas of IRU include the distal phalanx, metacarpophalangeal joint (medial condyle of the McIII and PSBs), proximal aspect of the McIII, carpus, especially the third and radial carpal bones, metatarsophalangeal joint (proximal aspect of the proximal phalanx and distal plantarolateral aspect of the MtIII and PSBs), the proximal plantar aspect of the MtIII, subchondral bone of the TMT and CD joints and the medial femorotibial joint (see Chapter 19).

PROCEEDING WITHOUT A DIAGNOSIS

Proper identification of lameness as the cause of poor performance and localizing the site(s) of pain can be challenging and relies heavily on experience. It is particularly important to differentiate lameness from interference because interference can cause signs that mimic lameness, lameness can result from interference, and lameness can cause interference. Horses on a line without obvious lameness and a negative response to diagnostic analgesia can be frustrating. Horses can become stubborn and react to equipment and twist and bend the head and neck, causing signs similar to being on a line. Occasionally, horses with tooth-related pain get on a line. An ocular problem is a rare cause of a horse being on a line. Trainers may use bridles with partial blinds or vision-restricting cups to control a horse on a line.

Simultaneous RF and RH or LF and LH lameness, or even primary hindlimb lameness, can be difficult because hindlimb lameness can cause a head nod mimicking ipsilateral forelimb lameness. Diagnostic analgesia should start in the hindlimb. In trotters with foot and carpal lameness the caudal phase of the lame forelimb is longer, and to avoid interference, the cranial phase of the ipsilateral hindlimb is shortened (hiking), mimicking hindlimb lameness. Pelvic hike abates when the source of forelimb lameness is localized. If the lameness problem is complex and frustrating, it is possible that a fresh perspective from a colleague or advanced imaging may help.

To differentiate lameness from interference gait abnormalities, phenylbutazone (4.4 mg/kg twice daily for 5 to 10 days) is administered (the bute test). Horses with pain should improve, whereas those with pure interference gait abnormalities should not. However, not all horses with musculoskeletal pain respond to NSAIDs, particularly those with chronic lameness or numerous compensatory problems. Alternatively, the veterinarian should medicate the suspected area and see whether performance improves because mimicking the maximal exertion of racing is difficult. A trotter on a line only going into the first turn may be helped by injection of corticosteroids around a mildly painful medial splint or into the middle carpal joint. Sometimes treating a different area between several races may allow a fortuitous discovery, but this requires good record keeping, and it may be expensive. Occasionally, horses with subtle or nondescript lameness or a rough gait are managed using a shotgun approach, and numerous intraarticular treatments are given simultaneously. This approach should be reserved for horses in which normal management procedures have failed and an important race is rapidly approaching. Sometimes a positive response to intraarticular corticosteroid injections results from systemic absorption and effect on a distant, rather than the intended, site.

A brief turnout period of 7 to 10 days is sometimes useful. In 2-year-olds, a decision often is made to stop training and give 3 to 4 months of turnout rather than risk compensatory lameness or fracture. The decision to stop training a horse should not be taken lightly. Getting an older horse back to the same level of racing is often difficult, even with a planned turnout period, and jogging the horse three to four times a week to maintain condition and range of joint motion may be best. The older the horse is, the more difficult it is to return the horse to racing. Older horses with chronic lameness do not thrive with rigorous training and often come out of a solo training mile lamer than after schooling or qualifying races. Older horses often are raced into fitness rather than trained rigorously. A common mistake is to train or race these horses too often.

A complete neurological examination should be performed in any horse with gait deficits and even some with overt lameness, if neurological signs are noticed concomitantly. EPM is frequently diagnosed, but positive identification of the source of neurological signs is difficult to make because serum and cerebrospinal fluid analyses are not accurate (see Chapter 11). The immunofluorescent antibody test (University of California, Davis, California, United States) ascribes a numerical value (titer) to the levels of antibodies to the organisms causing EPM and appears to be more accurate than the Western blot technique, and results of this test have correlated better with clinical signs in STBs suspected of having EPM. A common method to manage horses when all else fails is to treat for EPM and observe the results. Some horses improve despite having no overt neurological signs.

SHOEING AND LAMENESS

Shoeing to obtain ideal high-speed gait is an art, especially in trotters that are difficult to balance. The farrier must be a part of the lameness team. Veterinarians have to take a back seat to the trainer and farrier and cannot be

overtly critical of the shoeing approach. Sore front feet are common, and many approaches are used. Sometimes a simple shoeing change redistributes load away from a sore area, and a common approach in trotters is a switch from a half-round to a flip-flop shoe (see Figure 109-5). Classically, trotters are shod with more weight up front, whereas pacers are shod with more weight behind. Recently the tendency has been to lighten shoe weight in trotters and pacers in front and behind. The typical hind shoe of a pacer (a half-round, half-swedge) has been replaced by an aluminum shoe with a low toe grab. Aluminum shoes are used commonly in front in pacers. In trotters, heavy front shoes may predispose to interference injury and carpal lameness, and now aluminum shoes often are used behind, allowing a lighter shoe to be used in front. Light aluminum shoes with grabs allow maximal track purchase and increase speed, but they may worsen existing OA of many distal joints behind and in front. A STB can jog and train abnormally with a sprung shoe or a broken bar shoe. Special attention should be given to the medial half of the front foot because interference bruising is substantial.

A low-heel, underslung foot is not common in modern day STBs, although low-heel, long-toe conformation was previously favored in the erroneous assumption that it would increase stride length. When combined with heavy shoes, long toes prolong breakover, increase stress on the dorsal aspect of the forelimb, and predispose the horse to lameness. Using a shorter toe and more upright front foot is a major improvement in trimming trotters.

Quarter cracks and other hoof wall defects are common. Acrylic and composite repair of hoof defects have aided many sore-footed STBs. Acrylic often is applied to augment the hoof wall. In horses with thin walls, shoes are difficult to maintain, especially when shoes may be changed every 2 to 3 weeks. Overzealous application of acrylic can weaken a normal hoof wall.

TEN MOST COMMON LAMENESS CONDITIONS IN THE NORTH AMERICAN STANDARDBRED RACEHORSE

1. Front foot lameness
 2. Carpal lameness
 3. Metatarsophalangeal joint lameness
 4. Distal hock joint pain and other tarsal lameness
 5. Suspensory desmitis: forelimb and hindlimb
 6. Metacarpophalangeal joint lameness
 7. Splint bone disease
 8. Stifle joint lameness
 9. Rhabdomyolysis and muscle soreness
 10. Other soft tissue lameness: curb and superficial digital flexor tendonitis
-

SPECIFIC LAMENESS CONDITIONS OF THE STANDARDBRED RACEHORSE

Front Foot Lameness

Front foot lameness is the most common lameness condition. Palmar foot pain abolished using palmar digital analgesia is a common finding, but the veterinarian should keep in mind that palmar digital analgesia also abolishes

most of the pain associated with the DIP joint and toe and lower pastern regions. Occasionally, palmar digital analgesia can abolish pain associated with the fetlock joint. Palmar foot pain can be caused by a bruised heel, corns, sheared heel, hoof cracks, contracted heel, wall separations and gravel, stress remodeling and stress fractures, traumatic fractures, OA, or various combinations of these conditions.

Bruises, Corns, and Abscesses

Bruised feet can be caused by faulty conformation such as that seen in a large, flat-footed horse that develops bruising of the heel and bars. Small, narrow-footed horses are prone to quarter and heel cracks and a sore heel. Young STB feet are trimmed and pared and subjected to daily concussion on a firm and unforgiving surface. Aggressive paring can predispose to palmar sole bruising. Overt lameness may not be seen. Horses are often sore when starting from the barn and warm out of lameness after jogging a short distance. Because early carpal lameness can produce similar signs, careful hoof tester examination is necessary and often reveals profound sensitivity across the heel.

Base-wide, toed-out conformation causes overload of the medial heel bulb and quarter, and long, sloping pasterns cause overload of the palmar aspect of the foot. Shoes that are too narrow or those with short branches can cause sole bruising and corns. Horses that interfere (cross-firing or forging) are often shod with the inside branch of the shoe turned in to prevent grabbing and pulling of the shoe, and this can cause corns. Shoeing to correct interference is important but so is management of lameness that may lead to interference. Tubbing and soaking may compound the problem, creating a softer, more easily bruised sole. Poulticing may reduce inflammation initially, but continuous poulticing has the same undesirable result. The sole should be hardened with daily applications of an iodine-based paint, such as Rites paint, an iodine-ether preparation. Attention should be given to the stall bedding because an overly dry stall may lead to dry, cracking hoof walls. Digging out a bruise prolongs lameness and predisposes the hoof to abscessation. A wide web, concave inner surface steel bar shoe is applied if the horse can tolerate this much weight. A trainer may prefer a lighter aluminum bar or egg bar shoe. Full pads may afford protection for an upcoming race, but bruises cannot be reassessed, and sole paint cannot be applied. In trotters the flip-flop shoe is advantageous because the pad can be lifted and the sole painted, and without shoe branches the heel can spread. Deep-seated bruises can become corns; corns can fissure and crack; and bacterial invasion can cause infection. With abscessation, judicious paring to establish drainage is necessary, but the more sole that is removed, the longer it takes to heal. Soaking in warm water with Epsom salts (magnesium sulfate) and then wrapping with ichthammol (an iodine-based drawing salve) promotes drainage.

Sheared Heel

Quarter and heel cracks, wall separations, and a contracted heel can result from a sheared heel. Improper and asymmetrical rasping over time results initially in lowering of one heel bulb and later to vertical heel walls, a contracted heel, and flaring of the wall on the side of the lower heel bulb. With medial-to-lateral hoof imbalance, the vertical

heel strikes the ground first, and uneven impact causes structural breakdown between the bulbs of the heel. The heel bulbs are painful, and little resistance is offered to digital displacement of the bulbs in opposite directions. Corrective shoeing involves shoeing the steep side full and floating the quarter. The flared wall is shod tight and rasped off over several trimmings. For a horse with a long-toe and underrun heel predisposed to sheared heel, the toe should be shortened and the heel maintained. Recurrent quarter and heel cracks are common sequelae.

Hoof Cracks

Hoof cracks, depending on location, are known as heel or quarter cracks. Cracks may begin at the coronary band or at the bearing edge of the hoof wall. If the quarter crack extends to the sensitive laminae, local tenderness and variable lameness result. Horses with dry, shelly feet or vertical walls are predisposed to quarter cracks. Untreated chronic inflammation, inappropriate rasping of the periople, and application of excessive acrylic predispose horses to dry feet because exposure of horn tubules results in loss of moisture. Indiscriminate cutting of bars predisposes horses to a contracted heel and results in vertical walls. A vertical wall is more likely to crack than a normal one. Quarter cracks can develop if horses are shod with the web of the shoe set in. To manage quarter cracks, weight bearing is prevented by floating, and artificial support to the weakened and cracked wall is applied using a full or egg bar shoe. Extensive, deep, or painful cracks are repaired and stabilized. Acrylic patches are now preferred, but the crack must be prepared by paring and drying with iodine paint or gentian violet; otherwise, infection may develop.

Contracted Heel

A contracted heel can result from palmar foot pain rather than cause it. Dry, brittle feet cannot expand normally and may contract, as does a foot that has a long toe and low heel. When faced with a choice, farriers too often pick a shoe that fits tight (narrow), rather than full (wide), when the horse really needs a size in between. The wall inevitably grows to the small shoe and contracts. The indiscriminate use of acrylic results in heel contraction because the material restricts expansion. Acrylic should be placed on the weight-bearing wall surface only to repair broken or brittle walls for nail placement or for rebuilding low heels. The last shoe nail should be placed at the bend in the foot quarter, rather than in a more palmar location, to prevent restriction of heel movement. Other causes of palmar foot pain reduce weight bearing at the heel, leading to contraction. To manage a contracted heel, the quarter is softened, the toe is shortened, and an extended bar shoe that fits full (wide) is applied. Lowering the heel to achieve frog pressure is contraindicated.

Wall Separation and Gravel

Gravel is caused by separation of the white line at the quarter and heel and bacterial invasion. Lameness, insidious at first, progresses to nearly non-weight bearing. Digital pulse amplitude is increased, and the horse responds intensely to hoof tester pressure over the affected area. The coronary band or heel bulb becomes sensitive just before infection breaks out. Local therapy such as soaking and poulticing may hasten coalescence and proximal migration

of exudate. If pastern cellulitis occurs, broad-spectrum antimicrobial agents should be given. The horse is generally sound within 24 hours after drainage, but a full pad may be necessary to avoid repeat infection during wall healing. Wall separations and gravel are common complications to sheared heels and dry, brittle feet. Seedy toe is an infected wall separation at the toe.

Sidebone

Ossification of the cartilages of the foot (sidebone) is a rare cause of lameness. Ossification may be hastened in horses with poor hoof conformation, particularly in those with chronic medial to lateral hoof imbalance or in those in which interference injury occurs. Sidebone is found more often radiologically in aged horses with large, round, flat feet, but it may be seen incidentally in yearlings. If sidebone is painful to digital palpation, a bar shoe with heel clips and local subcutaneous injection of corticosteroids and Sarapin (High Chemical Company, Levittown, Pennsylvania, United States) may provide temporary relief. Interference injury may cause fracture and infection of a cartilage of the foot.

Fractures of the Distal Phalanx

Fractures of the distal phalanx occur most commonly in the LF lateral and RF medial palmar processes and are usually articular (Figure 108-4).⁷ Clockwise training and racing may account for asymmetrical location of fractures. Nonarticular palmar process and midsagittal fractures are rare. Predisposing factors include hard racing surfaces (most fractures occur during a race, more often in winter months), foot imbalance, impact on an uneven surface, and overloading. Fractures of the distal phalanx are unlikely single-event injuries and are the sequelae to maladaptive or nonadaptive remodeling of the distal phalanx that results from stress-related bone injury. IRU often is seen in the lateral aspect of the LF and medial aspect of the RF

Fig. 108-4 • Dorsomedial proximal-palmarolateral distal oblique xeroradiographic image of the right front foot of a Standardbred racehorse. There is a typical articular fracture of the medial palmar process (arrows) of the distal phalanx. The horse is shod with a bar shoe with clips.

Fig. 108-5 • **A**, Dorsal delayed (bone phase) scintigraphic image showing a typical distribution of increased radiopharmaceutical uptake of the Standardbred front feet. The left forelimb is on the right. **B**, Lateral delayed (bone) phase scintigraphic image of the left forelimb. This Standardbred was lame in the left forelimb, and lameness was localized to the lateral aspect of the distal phalanx. In the left forelimb, stress remodeling of subchondral bone of the distal phalanx was diagnosed. Increased radiopharmaceutical uptake involving the lateral aspect of the left forelimb and medial aspect of the right forelimb distal phalanx is thought to be caused by counterclockwise training and racing, and stress-related bone injury can lead to fracture in these locations.

distal phalanx in horses with lameness abolished by palmar digital analgesia but in which radiographs are negative (Figure 108-5).⁸ Most fractures of the distal phalanx occur in aged horses. Treatment includes application of a wide web, concave inner surface steel straight or egg bar shoe with two side clips on each side. Horses are given 3 months of stall rest and then 3 months of turnout in a small paddock. Most fractures are complete but nondisplaced; mild displacement results in a step in the articular surface. Fractures take months to heal, and some appear to develop chronic nonunions, although many horses return to racing soundness even with a radiologically apparent nonunion. Distal phalangeal fractures in the hind feet are unusual to rare but generally involve the medial plantar process and are articular in location.⁵ OA of the DIP joint often occurs, particularly in horses with displacement or nonunion, but unless severe, prognosis for racing is good. Osteochondral fragments of the extensor process of the distal phalanx are unusual, but arthroscopic removal of small fragments and repair of large ones are indicated. Prognosis is fair, but OA of the DIP joint can affect prognosis negatively.

Osteoarthritis of the Distal Interphalangeal Joint

The earliest sign of primary OA of the DIP joint is effusion. Effusion is also common in horses with nondescript foot soreness. Intraarticular injections of hyaluronan and corticosteroids are often performed into the DIP joint. Progressive OA can cause severe lameness, chronic fibrosis, and thickening of the DIP joint capsule, radiological evidence of proliferative changes on the dorsal aspect of the middle phalanx and extensor process of the distal phalanx, and narrowing of the DIP joint space.

Other Foot Lameness

Navicular disease is a rare cause of palmar foot pain. In 2-year-olds and early 3-year-olds, IRU in the navicular bone is seen in delayed (bone) phase scintigraphic images, indicating abnormal bone modeling, but rarely do radiographs show substantial changes, except for mild medullary increased radiopacity. Navicular bone fracture, cysts, and acute separation of bipartite navicular bone are diagnosed rarely in forelimbs and hindlimbs. Horses with bipartite bones or fractures have a poor prognosis, and palmar digital neurectomy is recommended. Keratomas in young racehorses are not seen, but they can occur rarely in broodmares or older STBs being used for alternative sporting activities.

Undiagnosed foot lameness—sore feet—is common. Horses have sensitivity to hoof testers and likely have soft tissue trauma, but a definitive diagnosis cannot be made. Treatment of the DIP joint with corticosteroids and hyaluronan, perineural injection of antiinflammatory agents, and shoeing changes are recommended.

Carpal Lameness

The carpus is the most common articular location for lameness and conformational faults. In 2-year-olds, carpal synovitis is common. High prevalence of carpal lameness is caused in part by racing young, immature STBs around tight turns on firm surfaces. The medial aspect of the middle carpal joint and the right carpus are predisposed to injury. Lateral injury of the carpus is unusual. Heat, effusion, and pain on careful palpation of the dorsal surfaces are common. Heat (the perception of warmth) on the dorsal aspect of the carpus is the earliest clinical sign of subchondral bone injury of the dorsomedial aspect of the middle carpal joint. Lameness varies with severity of injury, and horses carry the limb in an abducted position during advancement (see Chapter 38). Response to flexion varies, and diagnosis should be confirmed using intraarticular or median and ulnar analgesia. Secondary shoulder muscle soreness often develops. Horses warm out of lameness, and weeks to months may pass before consistent lameness is seen. Radiographs are usually negative or equivocal initially, but increased radiopacity of the third carpal bone and mild marginal osteophyte production can predispose the horse to small osteochondral fragments or slab fractures of the third carpal bone. The mere presence of increased radiopacity of the third carpal bone, however, is not diagnostic for subchondral bone pain because mild sclerosis is an adaptive response to race training (Figure 108-6). Diagnosis of subchondral bone pain as a result of maladaptive or nonadaptive remodeling is made using a combination of abnormal clinical and imaging findings. In a radiological study evaluating degree of increased radiopacity of the third carpal bone, exercised horses had significantly more increased radiopacity than nonexercised control horses, and lameness referable to the middle carpal joint developed more commonly in STBs with higher degrees of third carpal bone increased radiopacity.⁹ Thirty percent of STBs in the study developed lameness of the middle carpal joint.⁹ In a separate study the same investigators determined the importance of middle carpal joint pain in STBs and found carpal lameness to be present in 28% of STBs overall and in 56% of those with forelimb lameness.¹⁰ Carpal lameness was the most common reason for more

Fig. 108-6 • Dorsoproximal-dorsodistal digital radiographic image of the right distal row of carpal bones in a 2-year-old Standardbred filly that was sound and racing successfully at the time of this radiological study conducted as part of an examination before purchase (medial is to the right). Mild-to-moderate increased radiopacity of the radial fossa (between arrows) is seen as an adaptive response to training and racing. This filly continued to race successfully for the remainder of the 2- and 3-year-old racing years.

than 1 month of rest in STBs in race training. Few clinical signs such as effusion were present. Risk factors were faulty conformation and intense speed training.¹⁰ Diagnostic analgesia remains a most important aspect of clinical diagnosis, given the lack of early clinical signs associated with subchondral bone injury. Scintigraphic examination often reveals focal areas of IRU, usually involving the third carpal bone or the subchondral bone of the dorsomedial aspect of the middle carpal joint collectively; bilateral lesions are common (see Figure 19-16). Stress-related bone injury results in a continuum of subchondral and overlying cartilage damage, eventually leading to OA or osteochondral fragments. Rest is the best form of management but is usually unacceptable to trainers and owners. Topical counterirritation with iodine paints is still popular and is used with apparent success because blistering usually is accompanied by a reduction in exercise intensity. The administration of NSAIDs for 3 to 5 days and a brief period of reduced exercise (2 weeks) may be an acceptable compromise between the veterinarian and the trainer, but keep in mind that although a reduction in training intensity is helpful, bone cannot heal in 2 weeks, and pain may not subside. Intraarticular injections of hyaluronan or polysulfated glycosaminoglycans (PSGAGs) may reduce inflammation and theoretically may be useful in cartilage healing, but these often are used in a palliative rather than therapeutic manner, given a lack of synovitis in most horses. Injections may be of little benefit when pain originates from subchondral bone. Ten 2-year-old STBs with mild carpalitis were treated with three to five weekly intraarticular injections with PSGAGs (Adequan, Luitpold Pharmaceuticals, Inc., Shirley, New York, United States) and were compared with a control group receiving NSAIDs and topical counterirritation.¹¹ The treated group had substantially less carpal lameness during the ensuing racing season. All horses raced, but horses in the control group required intraarticular injections to maintain soundness. Early aggressive intraarticular therapy may forestall development of progressive OA in young STBs. Extracorporeal shock wave therapy has gained popularity as an adjunctive therapy in the management of STBs with subchondral bone injury and OA. With the exception of a palliative analgesic effect, the role of this

modality in potentiating healing remains unknown. The possibility exists that as a result of the analgesic effect horses could be continued in training well past the ability of injured bone to adapt.

Palmar foot pain may play a role in the development of carpal lameness in young STBs. Early carpal lameness is easier to treat if palmar foot pain is recognized early and managed aggressively. In horses with bruised bars and poor medial-to-lateral hoof balance, the application of wide web bar shoes reduces inflammation and signs of carpal lameness. In all ages of trotters, the flip-flop shoe appears to be effective in reducing clinical signs of carpal lameness. Small osteochondral fragments of the carpus are the most common fractures and involve the third and radial carpal bones and rarely other bones in the middle carpal and antebrachio-carpal joints. Arthroscopic surgical removal and PSGAG therapy after surgery are recommended. Frontal (dorsal) and sagittal slab fractures occur commonly, and repair using screws placed in lag fashion is recommended. Small, frontal slab fracture fragments can be removed. Although rest is an option in horses with nondisplaced fractures, internal fixation may shorten recovery period and reduce risk of recurrence (see Chapter 38).

Metatarsophalangeal Joint Lameness

The metatarsophalangeal joint is a common source of pain causing lameness in STBs, and diagnostic analgesia is usually essential for diagnosis.

Stress and Maladaptive or Nonadaptive Remodeling

Stress and maladaptive or nonadaptive remodeling of the metatarsophalangeal joint most often involves the distal, plantarolateral aspect of the MtIII, PSBs, and the proximal aspect of the proximal phalanx (see Chapters 19 and 42).^{6,12} Initially the horse has a variable, subtle, high-speed lameness, most commonly manifested around turns or by the horse making breaks. Later, grade 1 to 2 of 5 hindlimb lameness is seen at the trot in hand. Lameness can be localized to the metatarsophalangeal joint, but it does not improve with intraarticular treatment. Palpation findings are negative or equivocal. Horses show variable responses to flexion and have negative radiological findings but positive responses to diagnostic analgesia. The low plantar or lateral plantar metatarsal block is most effective, but horses may respond partially to intraarticular analgesia (and may require 12 mL of local anesthetic solution). Later, increased radiopacity and radiolucent changes of the plantarolateral aspect of the MtIII are seen on down-angled radiographic images. Ultrasonographic evaluation may reveal a defect in articular cartilage late in the disease process. Scintigraphic examination is the best way to establish a diagnosis and shows focal IRU involving the distal aspect of the MtIII (see Figures 19-6, 19-20, 42-1 through 42-3, and 42-6 through 42-9). The disease can affect both hindlimbs. The distal aspect of the MtIII appears at risk to develop stress-related bone injury before other sites in the metatarsophalangeal joint, possibly from anatomical variations or uneven loading during the full extension and landing phases of the stride. Shoe additives such as calks or grabs may play an adverse mechanical role. The metatarsophalangeal joint is a high-motion joint and subject to high-strain cyclic fatigue (repetitive loading) that is encountered during intense exercise around turns and on hard surfaces. This

continuum of stress-related bone injury can lead to OA and fracture (see Chapter 42).

Exercise intensity is reduced for 1 to 3 weeks. If lameness is prominent, a 3- to 4-month rest period is necessary. Exercise reduction allows the modeling and remodeling processes to equilibrate and microdamage to heal. A flat shoe is applied or the horse is left bare footed. Cold water therapy and the administration of NSAIDs (phenylbutazone or acetylsalicylic acid) appear helpful initially. Intraarticular injections of hyaluronan and PSGAGs may help, but early in disease, overlying cartilage damage and synovitis are not prominent, and response to intraarticular injections is minimal. When radiolucent changes and synovitis develop, response to intraarticular injections is better, but prognosis is worsened. Extracorporeal shock wave and radial pressure wave therapy may be useful in providing partial analgesia and may prolong training and racing. Bisphosphonate therapy is currently used for many conditions, including subchondral bone pain, OA, and other bone-related problems, but efficacy is unknown (see Chapter 42, page 490). In TBs there is a higher risk of catastrophic breakdown than in STBs, although the wisdom of training and racing a STB with chronic pain is certainly debatable. Whenever possible, frank advice must be given to trainers and owners about the long-term sequelae of continued training and racing a STB with a condition that may lead to OA.

Fractures

Acute, severe lameness is seen most commonly in STBs with fractures of the metatarsophalangeal joint, but some horses can race with incomplete fractures. Horses shorten the cranial phase of the stride, land on the toe, and rapidly compensate with other limbs. Often no effusion or pain on flexion is apparent unless a fracture is displaced. Diagnostic analgesia and examination in harness are avoided if

a fracture is suspected because comminution or displacement can occur. Radiographs, including flexed dorsoplantar or 125° dorsoplantar and flexed lateromedial images, should be obtained.

Midsagittal fractures of the proximal phalanx are most common, causing severe intermittent or severe unrelenting lameness, depending on fracture length and configuration. Fractures can be short, incomplete with mild periosteal proliferation on the dorsal aspect of the proximal phalanx (Figure 108-7) or long, incomplete or complete midsagittal fractures, fractures that break out of the lateral cortex, and comminuted fractures (see Figure 36-10). Horses with short, midsagittal fractures often race or train because lameness is intermittent and often abates after several days. Clinical signs precede radiological evidence of fracture for 7 to 21 days, and scintigraphic examination reveals focal IRU in the proximal aspect of the proximal phalanx (see Figure 19-20, C). Horses with short, midsagittal fractures can be rested or have internal fixation and have a good prognosis with either treatment.¹³ Long incomplete, complete, displaced, or comminuted fractures should be repaired. Prognosis depends on degree of comminution and displacement and whether a strut of bone is intact to which to attach fragments. Horses with comminuted fractures rarely race again and are at risk of infection, fracture displacement, and OA of the metatarsophalangeal and proximal interphalangeal joints and contralateral limb laminitis (see Chapter 35).

Dorsal plane (frontal) fractures of the proximal phalanx can be unilateral or bilateral, are most common in the RH, and occur in trotters and pacers (see Figure 42-11 and accompanying text). Fractures of the PSBs are common and most often involve the lateral PSB. Small medial abaxial fragments can be difficult to identify. Apical PSB fractures are most common, but abaxial, midbody, and rarely basilar fractures occur, and the combination of suspensory

Fig. 108-7 • Dorsoplantar (A) and flexed lateromedial (B) xeroradiographic images showing a short, incomplete, midsagittal fracture of the proximal phalanx (arrow). There is slight periosteal new bone on the proximodorsal aspect of the proximal phalanx seen in the flexed lateromedial image (white arrow). Radiological changes often lag behind clinical signs, and follow-up radiological and scintigraphic examinations often are needed to establish a diagnosis.

desmitis, and splint bone and PSB fractures is not uncommon. Horses show acute lameness after training or racing, with grade 3 to 4 of 5 lameness, and prefer to bear weight only on the toe. Effusion and a positive response to flexion are usually present, and the diagnosis is confirmed radiologically. Ultrasonographic examination of the SL should be performed to establish baseline information and assess prognosis. Surgical removal of apical, abaxial, and basilar fragments and surgical repair of displaced midbody fractures using bone screws or wiring techniques are recommended. Prognosis is guarded in trotters and fair in pacers that have raced before fracture. Horses in which fractures occur early in training appear to have a poor prognosis. Of 43 STBs with apical PSB fractures no difference in prognosis was found between pacers and trotters; 86% of fractures involved the hindlimbs. Prognosis was better in STBs with hindlimb PSB fractures than with forelimb injuries. Eighty-eight percent of horses that raced before injury raced after injury, whereas only 56% of those previously unraced raced after injury. Neither fracture fragment dimensions nor associated suspensory desmitis negatively affected outcome.¹⁴ These latter two findings are surprising given our experience.

Condylar fractures of the McIII or the MtIII occur, and fractures of the lateral condyles are more common than those of the medial condyles. Medial condylar fractures of the MtIII outnumber those occurring in the McIII. Clinical signs are similar to those caused by midsagittal fracture of the proximal phalanx, but diagnosis can be difficult unless good-quality radiographs with appropriate views are obtained. A flexed dorsoplantar or 125° dorsoplantar image should be obtained. Medial condylar fractures often spiral proximally and should be repaired, although even with repair there is a risk of catastrophic failure of the bone. In general, lateral condylar fractures of the McIII or the MtIII are best managed using surgical fixation, although STBs with short, incomplete fractures can be successfully managed conservatively. Regardless of management method, prognosis is favorable; 12 of 13 STBs with incomplete condylar fractures of the MtIII and 7 of 9 with incomplete condylar fractures of the McIII raced after injury.¹⁵ Four of six surviving horses with medial spiral fractures of the MtIII raced after injury.¹⁵ In that study, TBs were overrepresented and STBs were underrepresented when compared with the hospital population; TBs had significantly more lateral condylar fractures and forelimb condylar fractures than did STBs.¹⁵

Osteochondrosis

The metatarsophalangeal joint is a major site for osteochondrosis, and the most common manifestation is plantar fragmentation. A complete discussion of axial, articular fragments and abaxial, nonarticular fragments and other forms of osteochondrosis can be found in Chapter 42. Some debate exists over the management of STBs with axial, articular fragments and abaxial, nonarticular fragments and other fragments. Horses with axial, articular fragments and dorsal fragments respond well to arthroscopic removal and postoperative intraarticular injections of PSGAGs or hyaluronan. We believe that surgical removal prolongs racing careers and decreases metatarsophalangeal joint lameness. Some horses, particularly pacers, race successfully without surgery.

Proliferative synovitis, radiolucent defects of the PSBs, traumatic small osteochondral fragments of the proximal phalanx, and OA are discussed in Chapter 42.

Distal Hock Joint Pain and Other Tarsal Lameness

The hock joint is under considerable stress and strain, especially going into turns and with quick acceleration. Distal hock joint pain and progressive OA of the TMT and CD joints are common. However, distal hock joint pain should not be a default diagnosis, and careful lameness examination, including diagnostic analgesia, should always be performed. Injection of the “knees and hocks” is commonplace in the STB sport, despite our experience highlighting the importance of the metatarsophalangeal joint as a cause of hindlimb pain. Horses with distal hock joint pain warm out of lameness, often dramatically, because they may come out of the barn or paddock on the toe and eventually be able to train or race successfully. Horses show a mildly shortened cranial phase of the stride and a stabbing type of gait, with medial deviation of the limb during protraction and landing first on the outside toe (stabbing laterally), but this gait is not pathognomonic for distal hock joint pain. Palpation in a flexed position often reveals pain of periarticular soft tissue structures, and the Churchill test is often positive. Upper limb flexion is positive, but diagnostic analgesia is essential for diagnosis. Radiographs may show evidence of OA in older horses, but radiographs are negative or equivocal in most 2- and 3-year-olds. Changes are seen most often in the DM-PILO image, but dorsoplantar, lateromedial, and slightly off dorsoplantar images can be helpful. Scintigraphic examination confirms that OA of the TMT joint is most common, and changes are lateral and dorsolateral (Figure 108-8). Focal IRU is sometimes seen involving only the CD joint in horses that failed to respond to intraarticular analgesia of the TMT joint, emphasizing the need to block and treat each joint separately.

Treatment comprises intraarticular injections, NSAIDs, shoeing changes, and rest. Early, intraarticular hyaluronan is useful to decrease inflammation, and concomitant use of NSAIDs such as phenylbutazone (4.4 mg/kg PO daily for 5 days and 2.2 mg/kg PO daily for 5 days) is recommended initially. Later, as OA progresses, methylprednisolone acetate (80 mg/joint every 6 to 8 weeks) is most effective to manage inflammation. A series of intraarticular and intramuscular injections of PSGAGs also can be given. In horses with severe OA, 4 to 6 months of rest is successful, but recurrent lameness often mandates a limited racing schedule (10 to 15 starts/year). The toe is shortened, and a flat aluminum or steel squared-toe shoe is applied to allow easy breakover. All shoe additives are removed to decrease shear stress.¹¹

Slab fractures of the third tarsal bone and fractures of the proximal, dorsomedial aspect of the MtIII result from stress-related bone injury or from pathological fractures in horses with OA (see Chapter 44). Third tarsal bone fractures are the most common and are best seen on a DM-PILO image. Fractures of the central tarsal bone are usually oblique, involve the dorsal aspect of the bone, occur without concomitant OA, and are best seen in lateromedial images. Conservative management is recommended in horses with nondisplaced fractures, but displaced fractures should be repaired. Ninety-two percent of horses with slab fractures of

Fig. 108-8 • A, Plantar delayed (bone) phase scintigraphic image of the hocks. There is focal, nucleate (*right*) and intense (*left*) increased radiopharmaceutical uptake in the dorsolateral aspect of both tarsometatarsal joints (left hindlimb is on the left) in this 2-year-old Standardbred filly. **B**, Dorsomedial-plantarolateral oblique xeroradiographic image of the left hindlimb showing minimal changes (*arrow*). Lameness and scintigraphic evidence of distal tarsitis precede radiological changes by many months.

the third tarsal bone and 88% with slab fractures of the central tarsal bone raced after conservative management.¹⁶

The tarsocrural joint is often injected, but tarsocrural joint lameness is uncommon, except in young horses with osteochondrosis. Trainers often request injection of the upper and lower hock joints (tarsocrural and TMT joints), but lameness most likely is caused by pain associated with the distal hock joints. Bog spavin occurs most commonly in weanlings and yearlings, and radiological identification of osteochondrosis fragments prompts surgical removal. Most yearlings begin training without fragments. Although debate exists about the importance of tarsocrural osteochondrosis and lameness, we recommend surgical removal to resolve current inflammation, if present, and to prevent future lameness. However, osteochondrosis fragments are seen in some older racehorses in which neither lameness nor effusion is present. Tarsocrural lameness may occur without effusion, and diagnostic analgesia is necessary to differentiate the site of hock pain. Good-quality radiographs are essential to discover occult osteochondrosis fragments and fractures. The DM-PILO image is best for evaluating the cranial aspect of the intermediate ridge of the tibia and a slightly oblique dorsoplantar image (dorsal 5° to 7° lateral-plantaromedial oblique) is best to evaluate the medial malleolus. The most common sites for osteochondrosis are the cranial aspect of the intermediate ridge of the tibia, lateral trochlear ridge of the talus, medial malleolus of the tibia, medial trochlear ridge of the talus, and lateral malleolus of the tibia. Medial malleolar fragments appear to be increasing in importance, particularly in trotters, although a heightened awareness and improved imaging may be uncovering fragments in this location that may have previously been missed. Osteochondrosis fragments can be large, numerous, loose, and free floating, and cartilage damage can be prominent even in yearlings;

however, prognosis is good with removal. If distention of the tarsocrural joint is unexplained, osteochondrosis of the medial malleolus of the tibia should be suspected, and diagnostic arthroscopy is recommended. Small osteochondrosis fragments (dewdrop lesions) of the distal aspect of the medial trochlear ridge of the talus may be incidental but can cause lameness if displaced or if impinging on the central tarsal bone. Surgical removal is recommended.

Tarsocrural OA occurs in older horses (usually >5 years) and may be associated with osteochondrosis because fragments often are seen concomitantly. OA causes progressive lameness and effusion, but intraarticular analgesia should be performed to validate the source of pain. Large volumes of local anesthetic solution (30 to 50 mL) are necessary because pain is severe; false-negative responses occur if 10 to 15 mL is used. Radiographs may reveal prominent increased radiopacity and narrowing of the tarsocrural joint space, but end-stage OA can be present with only subtle radiological abnormalities (*Figure 108-9, A*). Scintigraphic evaluation reveals diffuse IRU on both sides of the tarsocrural joint and is useful to differentiate OA from sagittal fracture of the talus (*Figure 108-9, B*) or subchondral injury of the distal aspect of the tibia. Prognosis is grave.

Sagittal fracture of the talus is unusual. Acute, grade 3 to 4 of 5 lameness is localized to the tarsocrural joint by diagnostic analgesia, but often subtle tarsal lameness precedes fracture. Focal IRU is seen involving the talus (see *Figure 108-9, B*), and slightly oblique dorsoplantar images reveal subchondral lucency or fracture. Eight of 11 horses with sagittal fracture of the talus were STBs, and 7 raced after being managed conservatively.¹⁷

Enthesitis of the long, lateral collateral ligament of the tarsocrural joint, on the lateral aspect of the calcaneus, results in mild to moderate lameness and mild tarsocrural

Fig. 108-9 • A, In this dorsomedial-plantarolateral oblique xeroradiographic image, the tarsocrural joint space is narrow, indicating end-stage OA of the tarsocrural joint, but this radiological sign is difficult to recognize because proliferative changes are minimal. **B**, Flexed lateral delayed (bone) phase scintigraphic image of a different Standardbred with a sagittal fracture of the talus. With flexion, the area of moderate to intense increased radiopharmaceutical uptake moves with the talus and can be differentiated clearly from end-stage osteoarthritis (OA) or distal tibial subchondral trauma.

Fig. 108-10 • A, Lateral delayed (bone) phase scintigraphic image of a hock showing focal, moderate to intense increased radiopharmaceutical uptake in the calcaneus. **B**, Dorsoplantar xeroradiographic image showing proliferative changes associated with the collateral ligament attachment on the lateral aspect of the calcaneus (arrows).

effusion (Figure 108-10). Soft tissue swelling is easy to miss initially, and radiological changes lag behind clinical signs for at least 14 to 21 days; however, lameness abates or is improved considerably with tarsocrural analgesia. Scintigraphic examination reveals focal IRU in the lateral aspect of the calcaneus. Local injections and radiation therapy

may allow continued racing, but rest to allow enthesitis to subside is often necessary.

Injury of the fibularis tertius tendon anywhere from the midcrus to the distal tarsus can occur but is rare, and injury usually occurs at the insertion on the MtIII and the third tarsal bone. Soft tissue swelling is present, and the hock

can be pushed forward without concomitant extension of the stifle with the limb in standing position. Horses require 4 to 6 months of rest.

Inflammatory synovitis or infection of the tarsocrural joint is not uncommon. Prognosis depends on the extent of existing cartilage damage and the financial ability of owners to manage infection aggressively (see Chapter 65).

Suspensory Desmitis

Suspensory desmitis is the most common soft tissue injury and can be classified as unilateral branch desmitis, bilateral branch desmitis, body desmitis, and PSD. Suspensory desmitis is often an overload compensatory lameness condition because fatigue and improper landing occur in lame horses. Suspensory desmitis is seldom a single-event injury but is caused by accumulated damage over weeks to months (see Chapter 72). Diagnosis is made by careful palpation from the origin to the insertion of the SL with the limb in standing and flexed positions. The splint bones and PSBs are examined for associated injuries. One of us (JBM) has found that horses with core lesions are lamer, but exhibit fewer outward signs of inflammation, than those with peripheral lesions. Horses with suspensory branch desmitis are common and heal quicker (6 to 8 weeks) with lower recurrence than do those with body desmitis and PSD (4 to 6 months). Core lesions recur frequently. Because suspensory desmitis is often a compensatory injury, the primary lameness needs to be resolved. For example, OA and osteochondral fragments of the left carpus frequently cause suspensory desmitis of the RF in horses of both gaits, RH suspensory desmitis in trotters, and LH suspensory desmitis in pacers.

Ultrasonographic examination is critical in assessing the SL, and its entire length should be examined systematically. In hindlimbs, enlargement of the origin and body is more common than core lesions, and cross-sectional area measurements of the affected and contralateral limb are mandatory. Branches are evaluated for change in shape, loss of margin definition, central or marginal hypoechoic lesions, subcutaneous hemorrhage and edema, fibrosis and calcification, irregular contour (step line defects), and avulsion fragments of the PSBs. The interosseomedial ligament rarely is involved.

Forelimb unilateral branch desmitis results from toed-in or toed-out conformation, hoof imbalance, and uneven landing. To correct interference injury with knee knocking resulting from toed-out conformation, the hoof is commonly lowered on the inside, causing uneven loading and medial unilateral branch desmitis, whereas in horses with toed-in conformation, lateral unilateral branch desmitis occurs. Improper impact can occur from fatigue or if a horse is stopped suddenly. Lameness varies with severity of injury and presence of associated splint and PSB disorders.

Forelimb bilateral branch desmitis is caused by acute or chronic hyperextension of the metacarpophalangeal joint. Prognosis depends on the degree of fetlock drop seen when the contralateral limb is held in flexion. Concomitant PSB fractures can occur. Dorsal subluxation (flexion) of the proximal interphalangeal joint is seen in horses with bilateral branch desmitis and body desmitis, whereas palmar subluxation (extension) is seen in horses with distal sesamoid desmitis and loss of palmar support. If the axis of

the proximal interphalangeal joint is altered, the prognosis for racing is poor.

Forelimb body desmitis often begins just proximal to the bifurcation of the SL, and careful palpation reveals pain and mild enlargement. The first sign may be mild swelling, without lameness, and training and racing are often continued, leading to further suspensory desmitis. Horses often race successfully with chronic suspensory branch desmitis, but if desmitis progresses into the body, lameness becomes pronounced. There is a considerable difference in the potential for catastrophic breakdown injury with branch desmitis between TBs and STBs. Rarely, a STB develops catastrophic injury of the suspensory apparatus as a result of chronic suspensory desmitis, whereas continued racing with any suspensory branch desmitis is dangerous in TBs. Chronic enlargement and thickening of the SL often cause bowing of the splint bones, and concussion leads to fracture. Horses with recalcitrant swelling of the SL should be examined with ultrasonography because exuberant exostosis from fractures may encroach on the SL and cause swelling and pain.

Proximal palmar metacarpal pain is common and often called a check ligament problem, although genuine desmitis of the accessory ligament of the DDFT is rare. Palmar metacarpal pain can be caused by avulsion or longitudinal fracture of the McIII and stress reaction/stress fracture of the McIII, but PSD is most common. STBs often have pain on palpation of the proximal palmar metacarpal region and may have compensatory PSD, with primary lameness elsewhere. Lameness is noticed in the first half of the support phase of stride. An exaggerated head nod is often noted (JSM). A carpal type of gait may be seen. Lameness is most prominent when the affected limb is on the outside of a circle. Local analgesia and ultrasonographic examination should be performed. Radiographs are necessary to identify bone injury. Scintigraphic examination is useful to differentiate proximal metacarpal pain from carpal pain.

In hindlimbs, unilateral branch desmitis, bilateral branch desmitis, body desmitis, and PSD occur but less frequently than in forelimbs. Degree of lameness varies, and similar concerns exist about the MtIII, a splint bone, and a PSB involvement. Horses often land on the toe and are reluctant to put the heel down, especially if a concurrent pathological condition of the PSB exists. Suspensory branch desmitis often occurs first and can be managed successfully with continued work in some horses, but proximal progression toward the bifurcation and body causes substantial increase in lameness and may involve the splint bones, and often horses lose support of the metatarsophalangeal joint. Racing can no longer continue. Hindlimb suspensory desmitis is particularly important in young trotters. Many top 2- and 3-year-old trotters have been retired because of hindlimb suspensory desmitis. Second to carpal lameness, hindlimb suspensory desmitis is the most dangerous, career-limiting cause of lameness in trotters.

Early PSD can go unrecognized because of lack of obvious swelling. Local analgesia is critical for diagnosis. Once desmitis involves the body, swelling may be recognized, but damage is now extensive.

Inflammation can be suppressed, but rest is essential for healing. Rest is not well received by owners and trainers, who often exert pressure to keep a horse in work.

Cryotherapy is used to manage horses with suspensory branch desmitis and distal body desmitis. Horses with marginal lesions respond well but not those with core lesions. Cryotherapy decreases pain and seems to promote more or better-organized scar tissue. Periligamentous injections of sclerosing agents such as sodium oleate promote fibrosis and can be used to cause a swollen SL to “set up.” Periligamentous injections of corticosteroid mixtures reduce inflammation and lameness, but if training and racing continue, further damage occurs. Many naive owners lack understanding that the latest popular injection does not promote healing but simply masks inflammatory signs. Although horses may continue to race a few more starts, further damage inevitably occurs. Horses with PSD often can be managed using injections of corticosteroids, internal blisters, and, if available, radiation therapy, and if lameness is mild and support is not lost, racing may continue. Shock wave therapy has gained prominence and shows promise.

Rest is the best approach, and there is no substitute. Between 3 to 6 months of rest may be necessary to allow healing. A combination of stall rest, handwalking, walking in the jog cart, and swimming is recommended. We do not recommend turnout, but many horses are blistered and turned out, although this has been shown to be detrimental to healing. Healing progress is assessed by ultrasonography. Surgical management using a modified Asheim approach (ligament splitting, or desmoplasty) and osteotomy of fractured splint bones and PSB fragments is recommended. Desmoplasty and injection of fresh liquid bone marrow have been used successfully (MWR). Other intra-ligamentous injections with products such as platelet-rich plasma and stem cells have shown modest success. One of us (MWR) has performed bone marrow injection and fasciotomy on a limited number of top trotters with hindlimb PSD and body desmitis with modest success.

Prognosis depends on level of injury, gait (trotters worse than pacers), severity of injury (poor prognosis with fetlock drop), and associated bony pathological conditions. Unless the SL is totally disrupted, prognosis for racing is good, but racing class is an important consideration because few STBs return to the same or improved race class after sustaining suspensory desmitis (Figure 108-11).

Metacarpophalangeal Joint Lameness

Fatigue from underconditioning and other factors causing overload may lead to hyperextension of the metacarpophalangeal joint. Hyperextension leads to injury of the dorsal aspect of the joint, such as small osteochondral fragments of the proximal phalanx and proliferative synovitis, and to injury of the palmar aspect of the joint, such as fractures of the PSBs and suspensory branch insertional injury. Traumatic disruption of the suspensory apparatus is rare but usually involves rupture of the SL. Stress-related bone injury of subchondral bone leading to OA and fracture occurs in the metacarpophalangeal joint, as described for the metatarsophalangeal joint. In a STB with normal conformation, metacarpophalangeal effusion should be a red flag (a barometer), often a sign of compensatory lameness. Young horses often have bilateral metacarpophalangeal synovitis secondary to palmar foot pain because toe-first landing overloads the joint. Corrective trimming and shoeing often helps. In older horses unilateral carpal lameness

often causes contralateral metacarpophalangeal synovitis. Primary lameness of the metacarpophalangeal can begin when horses break stride, stumble, or stop quickly.

OA and stress-related bone injury are the most common problems of the metacarpophalangeal joint. Early radiographs are usually negative, but radiolucency and increased radiopacity of the distal medial aspect of the McIII develop later. Scintigraphic evidence of IRU is more prominent medially, unlike in the metatarsophalangeal joint, in which IRU is more common laterally. In older horses (about 4 years of age) with progressive severe OA, narrowing of the medial joint space indicates severe cartilage damage. Owners are incredulous that the horse has end-stage OA because lameness can be acute and severe, and fracture often is suspected.

Early OA is treated using intraarticular injection of hyaluronan alone or a combination of hyaluronan and PSGAGs. The latter is preferred, and three to four weekly injections are combined with a reduction in exercise. Horses that do not respond may have proliferative synovitis, usually seen in older horses with chronic OA. Injecting the joint in the dorsal pouch may be difficult, and little synovial fluid may be present. Surgical resection of synovial pads and postoperative intraarticular injections of PSGAGs are recommended.

Fractures and osteochondritis dissecans occur, but palmar fragments are rare (see Chapter 36).

Splint Bone Disease

Exostoses and Fractures of the Second and Fourth Metacarpal Bones (Splints)

Splints are a common problem in 2- and 3-year-olds (see page 1018). Poor conformation and hard track surfaces predispose horses to splints. Whether tearing of the interosseous ligaments occurs is unknown. Medial splints are most common. Yearlings can begin training with dormant, so-called field splints that become active as training advances. Splints rarely cause severe head nodding lameness, but put a horse on a line and signs become worse as work progresses. Splints on the abaxial surfaces of the McII and McIV are visible and can be palpated readily, but those on the axial surfaces require the limb to be lifted to relax the SL. Axially-located splints cause more obvious lameness than do abaxially-located splints.

Management includes reducing inflammation and limiting callus. Cold-water therapy and poultice should be applied, and horses are given NSAIDs. Blistering and external heat therapy may be contraindicated if reduction in the size of the callus is desirable. Ionophoresis with corticosteroids is successful. Perilesional injection of corticosteroids and cryotherapy are used successfully. Cryotherapy is a common therapeutic option often performed in STBs, but after the procedure local pain and inflammation persist, complicating palpation during reexamination. In these STBs, resolution of signs of lameness or other horse-related factors, such as a reduction or cessation of being on a line, is often used as evidence of clinical improvement. Cryotherapy may need to be repeated, and if necessary additional local therapy can be given once cutaneous sores from the procedure heal. If signs fail to abate, a fracture may be present. Improper toe-heel impact and medial-to-lateral hoof imbalance predispose horses to splints. Chronic

Fig. 108-11 • Images of a 3-year-old Standardbred colt pacer in May after being trained and qualified for racing; the colt had won divisional honors the previous year but developed substantial (3 of 5) left hindlimb lameness as a result of complex injury in the proximal plantar metatarsal region. **A**, Delayed phase lateral (left) and plantar scintigraphic images showing focal, intense increased radiopharmaceutical uptake in the proximal, plantar aspect of the third metatarsal bone (MtIII) indicative of bony injury at the origin of the suspensory ligament (double-headed arrow). **B**, Dorsoplantar digital radiograph (lateral is to the left) of the left proximal metatarsal region showing increased radiopacity (arrow) and mild radiolucency (arrowhead) of the MtIII; neither avulsion nor longitudinal fracture was seen, but changes of this magnitude in bone indicate the lesion is chronic. **C**, Transverse (left) and longitudinal ultrasonographic images acquired with the transducer medial to the plantar midline showing enlargement (double-headed arrow) of the proximal aspect of the suspensory ligament (cross-section area measured 2.4 cm²) and a large hypoechoic region (arrowheads). This colt was retired from racing.

splint disease in older horses is almost always related to palmar foot pain. Aggressive therapy for palmar foot pain and restoring normal hoof strike is critical. Direct trauma from interference and breaking must be prevented.

Fractures of the McII and the McIV can be caused by direct trauma. Interference injury can cause fracture of the McII, and accidents involving carts and other equipment predispose horses to fractures of the McIV. If fractures are located proximally and displacement exists, surgical fixation using small plates and screws is best. McIV fractures can heal functionally without fixation. Most distal splint

bone fractures are secondary to suspensory desmitis. Exuberant callus can impinge on the SL. Fracture callus and fragments should be removed.

Exostoses and Fractures of the Second and Fourth Metatarsal Bones

Exostoses most commonly involve the MtII, but chronic painful splint exostoses are not as common as in the forelimb. Perilesional corticosteroid therapy is recommended (80 mg of methylprednisolone and 8 mL of Sarapin, (High

Fig. 108-12 • A, Caudocranial digital radiographic image of the left stifle of a 4-year-old Standardbred (STB) trotter with marked narrowing of the medial femorotibial joint (MFTJ, *arrow*). Radiological evidence of narrowing on a well-positioned caudocranial image is the earliest sign of osteoarthritis (OA) of the MFTJ. **B,** Advanced OA of the MFTJ is seen in this caudocranial image of a 9-year-old STB pacer. Absence of an obvious MFTJ space (*arrow*), marginal osteophyte formation (*arrowheads*) of the distal, medial aspect of the femur and proximal medial aspect of the tibia, and radiolucency of the distal aspect of the medial femoral condyle can be seen. This horse was 4 of 5 lame in the left hindlimb, and the prognosis for racing is grave.

Chemical Company). Fractures of the MtII and the MtIV occur occasionally and usually result from direct trauma, but distal splint fractures can be secondary to suspensory branch desmitis. Fracture fragments should be removed.

Stifle Joint Lameness

The stifle joint often is incriminated as a source of pain, but diagnostic analgesia identifies a problem in the more distal part of the limb. OA of the medial femorotibial joint is the most important stifle lameness, but osteochondrosis should be considered in young horses. OA is a progressive disease beginning in late 2-year-olds, and degree of lameness varies from grade 1 to 4 of 5. Distention of the medial femorotibial joint capsule is an important finding, but in some STBs this is a subtle finding. The limb may be carried forward slightly lateral or outward during the cranial phase of the stride. The cranial phase is shortened, and lameness is worse in the turns. Radiographs are usually negative or equivocal in 2-year-olds, and arthroscopic evaluation reveals generalized cartilage thinning and fissure formation. Later, in caudocranial radiographic images, narrowing of the medial femorotibial joint space and mild osteophyte formation on the proximal medial aspect of the tibia and distal medial aspect of the femur are visible ([Figure 108-12, A](#)). Scintigraphic examination can confirm extensive OA. Diffuse IRU involves both sides of the medial femorotibial joint and is best seen in a caudal image, although if extensive IRU can be seen in a lateral image as well. Arthroscopic evaluation at this time reveals exposed subchondral bone and severe synovitis, but therapeutic value of arthroscopy is negligible. If the diagnosis of OA is made in a 2-year-old, a period of 3 to 4 months of rest is recommended. The stifle joint often is injected in horses without stifle lameness, and few untoward effects are seen. Treatment of STBs with OA of the medial femorotibial joint with methylprednisolone acetate is contraindicated early in the course of the disease. Although the drug is effective and allows continued

racing, OA can progress rapidly, resulting in severe lameness. Hyaluronan (40 mg) and isoflupredone acetate (4 to 6 mg) or triamcinolone acetonide (4 mg), interleukin-1 receptor antagonist protein, or PSGAGs (750 to 1000 mg) are preferred, and although they are less effective than methylprednisolone acetate, they decrease inflammation and prolong the racing career. Systemic administration of PSGAGs or hyaluronan is helpful. Methylprednisolone acetate is necessary for older horses with advanced OA, but if no improvement is seen, the racing career is usually over (see [Figure 108-12, B](#)). Once severe lameness occurs, rest may improve comfort slightly, but horses will not tolerate training again. Trotters can tolerate racing with more advanced OA than can pacers.

In young horses osteochondrosis can cause lameness and effusion in early training, prompting radiographic examination, but signs of osteochondrosis often are seen in weanlings and yearlings, and surgery is performed before training begins. Osteochondritis dissecans of the lateral trochlear ridge of the femur is most common; it causes considerable effusion of the femoropatellar joint and if bilateral may cause a bunny-hopping gait. Surgical treatment, 4 to 6 months of rest, and intraarticular therapy are recommended. Prognosis for racing is good unless lesions are severe or cartilage damage of the patella is advanced. Subchondral bone cysts most commonly involve the medial femoral condyle but can occur in the proximal aspect of the tibia. Lameness is often progressive, with horses first being on a line. Surgical debridement of the cyst is recommended, although injection of corticosteroids beneath the lining of the cyst and into the cyst cavity under arthroscopic guidance can be used. After debridement, lameness persists for several months, but this approach may be a better long-term solution. Horses need a minimum of 6 to 8 months of rest to allow healing and for lameness to abate. Prognosis is fair (70%) for successful racing.

Rhabdomyolysis and Muscle Soreness

We divide muscle lameness into metabolic disease (recurrent exertional rhabdomyolysis [RER]) and nonmetabolic disease (muscle soreness). Signs vary, but horses appear stiff and hindlimbs are not fully engaged in the stride unilaterally or bilaterally. Palpation often reveals muscle pain but must be done carefully because aggressive, sudden, and deep palpation elicits false-positive responses.

RER occurs more commonly in females and can cause swollen muscles. Overt clinical signs of tying up after racing and training can be seen, but subclinical RER can be a cause of poor performance. Myoglobinuria and elevation of serum creatine kinase (CK) and aspartate transaminase (AST) levels are diagnostic. Horses are managed initially with intravenous fluids, NSAIDs, tranquilization, and methocarbamol (22 mg/kg intravenously [IV] or 33 mg/kg PO twice daily). Care must be taken when using acetylpromazine and methocarbamol simultaneously because effects may be additive, and horses may act severely tranquilized (JSM). Walking is recommended in horses with mild RER but is contraindicated in those with severe RER. Dantrolene sodium (2 mg/kg IV or via nasogastric tube) and intravenous dimethyl sulfoxide solution are recommended in horses with severe RER. Large quantities of intravenous or oral fluids should be administered. After an acute episode, signs may recur or subclinical myositis may persist, reflected by elevations in CK and AST concentrations. Enzyme levels should return to baseline before intense training or racing resumes.

In horses with subclinical RER or those with recurrent acute episodes, we recommend a management protocol that includes a reduction in carbohydrate intake, especially

before exercise, a high-fat diet, vitamin E and selenium supplementation, supplementation with oral potassium, and a regular 7-day exercise program combining jogging, brief periods of intensive training, and paddock exercise, if feasible. Chronic administration of dantrolene sodium (2 mg/kg) or phenytoin (8 to 10 mg/kg PO twice daily) is recommended, but racing jurisdiction rules must be followed.

Nonmetabolic myositis is common, and gait is similar to that described for stifle lameness. Signs are similar to RER, but serum CK and AST levels are usually within or just above normal limits. The middle gluteal muscle and associated tendons commonly are affected unilaterally or bilaterally. Myositis may be a secondary problem or a primary source of pain after traumatic injuries such as accidents during transport, paddock injuries, slipping while racing on muddy or other undesirable surfaces, or by making a break. Horses are managed initially with muscle relaxants, NSAIDs, and rest (5 to 7 days). Horses with chronic soreness are treated with an internal counterirritant or corticosteroids injected strategically in the sore areas (see Chapter 88).

Curb and Superficial Digital Flexor Tendonitis

Other soft tissue injuries such as curb and superficial digital flexor tendonitis occur commonly. Curb in the STB is discussed in detail in Chapter 78. Superficial digital flexor tendonitis is discussed in detail in Chapter 69. Surgical management using desmotomy of the accessory ligament of the superficial digital flexor muscle (superior check desmotomy) and annular desmotomy if tendonitis involves the distal metacarpal region are recommended.

Chapter 109

The European and Australasian Standardbreds

THE EUROPEAN STANDARDBRED

Fabio Torre

DIMENSIONS AND CHARACTERISTICS

The European Standardbred (STB) is historically the result of different crosses between the classic American bloodlines and European families. The French STB is known for its stamina and aptitude for long distances. The American-derived families, however, have been selected for speed and racing at a fixed distance of 1 mile and are represented more widely in Italy and Sweden. Several countries (especially France, Italy, Germany, and the Scandinavian countries) have developed individual bloodlines and today

are able to produce good-quality STB trotters. In Europe no races are available for pacers. In Table 109-1 the STB population and racing activity of different European countries are listed.

Europe has a large number of racetracks for STBs, and they are characterized by different circuit lengths, surfaces, and designs. Half-mile tracks have been replaced progressively by 1-km ($\frac{3}{4}$ -mile) tracks, and no 1-mile racetracks (with the exception of training centers) are present in Europe. The most characteristic and popular racetrack is the Plateau de Gravelle in Vincennes, Paris, where the Prix d'Amerique is held. The track surface is made of pressed charcoal powder; slopes and descents are present; and the circuit is egg-shaped, which is unique in Europe, where other racetracks have a regular design. Another famous French racetrack, Cagnes-sur-Mer in Nice, is well known for being 1200 m in length and for hosting the Criterium de Vitesse, one of the main European free-for-all races. In Sweden, Solvalla racetrack in Stockholm represents the heart of the Swedish STB racing, and in late May the multiple-heat race Elitlopp is held. In Norway, in addition to well-developed STB racing (the main racetrack being Bjerke near Oslo), races for Warmblood horses (a breed historically devoted to hard work but now genetically selected for speed) are still popular and meet the special interest of the local public.

Italy	25	11	13	0
Norway	9	1	7	0
Sweden	26	1	25	0

Data from UET (European Trotting Union), update December 2000.

*The total number includes all racetracks in which at least 1 day of racing is held, but less important, occasional, and fairlike tracks (which are especially popular in France) are not considered in the subsequent columns.

A variety of track designs and purposes are present in Europe. For example, a large number of small country tracks are found in France, and local races are organized in a fairlike fashion, whereas the main racing activity is concentrated in Paris. In Italy, however, important races have a more even distribution among racetracks, Milan and Rome being the main places. In Table 109-2 the distribution of racing tracks in the main European countries is summarized.

Differences exist in availability of prize money among different countries, and this makes France and Italy the most attractive countries for trainers and owners. A number of well-known trainers started to move in the early 1980s toward France and Italy, especially from northern Europe, and this has enhanced the exchange of experiences between trainers and veterinarians.

Prize money distribution among horses of different ages has strongly influenced racing, especially in Italy, where 2- and 3-year-olds have the richest races. Higher purses for younger horses have also affected breeding programs and have stimulated an interest in many of the orthopedic problems affecting young horses, especially osteochondrosis, which has been studied widely in northern Europe.

APPROACHING LAMENESS PROBLEMS

Only STB trotters are allowed to race in Europe, and this makes the trainer's work more challenging. Any possibility to switch gaits or to move an unnaturally fast gaited trotter to a potentially good pacer is precluded. When the fast gait is compromised by biomechanical problems and substantial interference between limbs (unlike in the pacer), corrections aimed at avoiding interference are attempted. Finding a solution for mechanical problems is not always possible, and corrective shoeing that alters the natural gait may cause compensatory lameness in different locations.

A series of mechanical limitations may be present at the beginning of training, and relatively soon they are followed by pain-related problems, usually affecting joints and less frequently digital flexor tendons and the suspensory ligament (SL). A less than 100% natural trotting athlete is more likely than a natural trotter to have its gait totally compromised, even by a mild subclinical lameness problem, and consequently gait limitations increase. However, anything that is attempted by the trainer to improve gait (corrective shoeing, special equipment that prevents turning the head and neck toward one side, or shifting the hindlimbs toward one shaft) forces the horse to a nonnatural fast gait and

often results in lameness. In fact, when a nonnatural gait is forced, the end result is usually that a single limb (or a biped) is overloaded, and the uneven loading is exacerbated by the progression of training.

When young horses start training, they frequently have been subjected to basic lameness and radiological evaluations. This allows trainers the opportunity to treat conditions such as osteochondrosis or to be aware of other abnormalities. Prepurchase radiographic examinations and, when needed, preventative arthroscopic surgery (mostly for osteochondrosis of the tarsocrural joint and osteochondral fragments in the fetlock joints) are now practices that have received general acceptance. The reason to operate early is to have the horse rested before any training program is started. In yearlings eligible for autumn sales, it is important to perform surgery early to have presale radiographs without evidence of osteochondral fragments and to decrease effusion before the sale.

When moderate gait anomalies are present, experienced trainers usually give the horse time and keep going with a light exercise program instead of making radical changes. This allows, in many horses, a complete maturation of the equine athlete, and when the growth is complete and the muscular function well conditioned, the gait in many horses automatically improves without injuring the immature skeleton. Shoeing is also central in early training. Light plastic shoes are ideal to allow foot growth and expansion and to minimize trauma in the early phases of fast training.

LAMENESS EXAMINATION

Horses with acute, severe lameness should be allowed to rest. Radiographs are frequently diagnostic, revealing the most common severe musculoskeletal injuries affecting trained STBs, such as incomplete sagittal fractures of the proximal phalanx, fractures of the proximal sesamoid bones (PSBs), splint bone fractures, fractures of the third or radial carpal bones, fractures of a palmar process of the distal phalanx, fractures of the lateral condyle of the third metacarpal bone (McIII), slab fractures of the third tarsal bone, and stress fractures of the palmar aspect of the McIII or the plantar aspect of the third metatarsal bone (MtIII). Apical fractures of the PSBs are a common injury in young STBs, and the lateral PSB in the hindlimbs is the most common location.¹

The conditions mentioned previously represent injuries of the racing STB requiring rest or surgical repair. More commonly the veterinarian is consulted for mild or obscure lameness, gait disturbances, or poor performance. In any case, a thorough history is mandatory before the lameness examination is initiated.

A basic lameness history must include the following:

- What is the trainer's complaint?
- What is the horse's gait (naturally born vs. artificial trotter)?
- Describe the shoeing management: recent changes, difficulties in combining appropriate shoeing and fast gait, ideal shoeing for the horse, and attempts at correcting the problem.
- What is the horse's recent performance?
- When was the onset of the problem and correlation with previous lameness, if any?

- When does the problem arise during the race? Does the horse worsen in the turns or on the straight? Is the horse better at the beginning of the race and does it worsen at the end?
- Is the horse lame after the race?
- What about the day after the race?
- How is the horse during daily jogging (a question best addressed to the groom or assistant trainer)?
- How does the horse behave when trained clockwise (although races are counterclockwise)?
- Is the horse better when trained on a straight track, when available?
- Does the problem worsen on a particular racetrack and specifically on hard tracks?
- Is the horse on a line or on a shaft?
- Does the horse break stride? If so, when? At the start, approaching turns, in turns, coming out of turns, or in the straightaway?
- Does the horse deviate left in the turns and right on the straight lines? Does the tendency worsen at the end of the race?
- Has the horse been submitted to any previous lameness examination?
- Was the horse subjected to any previous treatment with paints, ointments, or local injections, and did the horse improve with therapy?
- Was any other problem diagnosed or suspected (exercise-induced pulmonary hemorrhage, rhabdomyolysis)?

Concerning conformation, the clinician should check the following:

- Foot conformation (club foot or low heel, toed in, toed out, hoof wall angle, correction of the lateral-to-medial balance, quality of the horn, characteristics of the sole and quarters, type of shoeing). Club feet may indicate osteoarthritis (OA) of the distal interphalangeal (DIP) joint. Toed-out horses have the most frequent gait disturbances because they tend to hit the contralateral carpus or the ipsilateral metatarsal region. Toed-in horses have less important gait problems, but the uneven distribution of the weight is likely to produce lameness associated with the middle carpal joint or suspensory desmitis.
- Potentially clinically significant conformational abnormalities include torsional defects proximal to the hoof (fetlock and carpus and, more rarely, the tarsus), uncorrected angular limb deformities, offset (bench) knees, tied in behind the knees, straight conformation of the hindlimbs. Any of these abnormalities invariably produces secondary injuries such as suspensory desmitis, superficial digital flexor (SDF) tendonitis, and middle carpal joint lameness.
- Conformation of the foot is important. Asymmetrical foot size is often a consequence of reduced weight bearing and lameness on one side, and the smallest foot is generally on the lame side.

Palpation

Many clinicians spend little time palpating a lame horse, a practice that I believe is a mistake. Areas of warmth (heat), especially in the hoof wall, must be detected, and regions of special interest include the fetlock joints, the

metacarpal and metatarsal regions, carpus, hock, stifle, and back.

In the forelimb, the DIP joint capsule just above the coronary band is palpated to detect effusion. The character of the digital pulse is evaluated and compared between limbs.

Hoof tester examination can be considered part of palpation. When possible, feet are first tested without removing the shoes, and ideally the horse should be kept shod until any examination in movement is completed. When diagnostic analgesia is needed, hoof testing must precede palmar digital analgesia, and shoes may be removed temporarily if bar shoes or pads prevent accurate testing. These six points are tested in each horse: lateral and medial quarters, lateral and medial middle sole, and lateral and medial toe. Testing the frog rarely produces useful information, and squeezing the quarters from lateral to medial with hoof testers may cause pain unrelated to the primary lameness.² Pain arising from the quarters, especially mild pain medially, should not be overrated because this region is frequently sensitive to hoof testers in normal horses. The contralateral foot may serve as a reference. In my experience the right medial quarter is the most common region to find pain elicited by hoof tester examination in STBs, and this is probably secondary to the counterclockwise direction of racing. This may be a clinically significant finding, but generally a painful response is considered more important when it arises from the toe or from the lateral side of the sole. When shoes are removed, a further evaluation of the lateral-to-medial balance is performed. The sole itself is observed, and when it appears flat and painful, this may correlate with type of shoes and padding that are used. Overzealous padding may add to, rather than relieve, pressure on the sole. A leather or rubber layer may allow sand to pack quickly under the pad and create pressure and secondary bruises. These horses are better managed with shoes in which the contact is limited to the hoof wall and no contact is made with the sole.

In the forelimb the fetlock joint is examined for effusion, alteration of the dorsal outline, and enlargement of the suspensory branches. The latter are palpated carefully with the joint flexed. Each branch is pressed gently axially, and alterations in consistency and pain response are noted. Range of motion of the fetlock joint is assessed. In a normal STB, the fetlock joint can be flexed up to 90 degrees (angle between the McIII and the proximal phalanx) without eliciting a painful response. With one hand holding the dorsal pastern region, the dorsal aspect of the fetlock joint can be palpated further by using the other hand to compress the dorsal joint capsule against the bony prominences of the sagittal ridge and condyles of the McIII. Horses with osteochondritis dissecans (OCD) or a hypertrophic synovial pad exhibit a painful response. The bony profile of the McIII must be followed with fingers to detect painful areas in the dorsal, lateral, and medial aspects. Palmar soft tissues are evaluated with the limb in a weight-bearing position and while being held off the ground. Each structure is palpated accurately to detect heat, pain, and edema in horses with acute lesions or fibrotic consistency and adhesions in those with chronic conditions. Fingers must be pressed firmly, deep in the proximal palmar metacarpal region, where pain originating from the proximal aspect of the SL is hard to detect. The carpus is better evaluated by

holding the limb in a moderate degree of flexion. Careful digital palpation along the dorsal aspect should be performed. Of particular importance is the dorsomedial aspect where a thickened joint capsule and painful response correspond to the common finding of OA of the middle carpal joint. Palpation of the forelimb proximal to the carpus is rarely helpful. Elbow and shoulder lameness are rare, and bicipital bursitis has seldom been reported.

In the distal aspect of the hindlimb, palpation is similar to that described for the forelimb with the exception that foot lameness is less important. The metatarsophalangeal joint region is best evaluated while holding the limb in a semiflexed position. When the proximal metatarsal and distal tarsus regions are palpated, some false-positive painful reactions frequently are elicited, especially on the medial aspect. This pain frequently is overemphasized in horses with back pain, especially when the trainer thinks the horse has primary lameness in the tarsus. Effusion of the tarsocrural joint often indicates the likely presence of osteochondrosis (OC). The stifle must be palpated deeply and carefully because the joint is complex, but the structures that can be assessed are limited. The femorotibial joints seldom appear distended, but effusion of the medial femorotibial joint is an important abnormal clinical sign. More frequently, joint effusion is limited to the femoropatellar joint, but because the femoropatellar and medial femorotibial joints communicate, inflammation in one may result in effusion of both. With the exception of acute trauma, painful responses to palpation are rare in this area, even from the patellar ligaments that are identified easily. On the medial side, scar tissue and irregularities or enlargement of the medial patellar ligament may suggest previous desmotomy. When associated with femoropatellar effusion, the latter sign may suggest apical patellar fragmentation, and radiographic examination is indicated. The stifle can be flexed only in unison with most other hindlimb joints, so a painful response is not specific. With moderate flexion the medial collateral ligament can be stressed by the veterinarian pulling the tibia in a lateral direction with both hands and pressing the shoulder against the femur.

Palpation of the back is aimed at evaluating pain arising from joints (intervertebral, lumbosacral, sacroiliac, and sacrococcygeal), nerve roots, and muscles. The latter are the most likely origin of pain elicited by palpation, but other problems must be ruled out if associated clinical signs (atrophy, asymmetry) are present. Pain in the gluteal area may be secondary to many problems, including straight hindlimb conformation, hock or stifle pain, sore feet, gait imbalance, and stiff corrective harness equipment. Therefore pain in this area should not be treated as a primary problem unless a thorough clinical examination has ruled out other sources of pain.

Movement

After palpation, the horse is examined during movement. I commonly tranquilize each horse I examine for lameness. Tranquilization (10 mg of acetylpromazine maleate intravenously) improves the possibilities of handling the horse and lowers the risk of injuries to the veterinarian. Furthermore, the horse appears less stiff; mild lameness becomes somewhat more obvious; and the horse stands better for radiographic or ultrasonographic examination. The trainer must be consulted before injecting a tranquilizer because

this practice may preclude racing because of doping regulations (the term used in Europe for a blood or urine drug test for a prohibited substance). Lameness is rarely detectable at the walk, but it is important to observe the way the horse lands with each foot to identify lateral-to-medial hoof imbalance. The horse is then trotted in a straight line on a firm surface, and the character of movements is observed. Abduction or circumduction of forelimbs is considered characteristic of carpal lameness because the horse appears to attempt to avoid flexion. In the hindlimb, stiffness has been related anecdotally to distal hock joint pain but in fact is not a specific sign. In horses with pain arising from the distal part of a hindlimb (frequently the metatarsophalangeal joint), the horse tends to moderately overflex the hock and stifle to shorten the weight-bearing phase of the stride.³ In horses with more severe lameness, drifting forward of the sound limb is observed, and a drop of the fetlock joint is easily seen. Abduction of the hindlimb is thought to be related to stifle lameness.

Flexion tests are used to supplement findings during movement and are similar to those used in other sports horses. Flexion of the carpus is accomplished by pulling the metacarpal region laterally, and the clinician's elbow may act as a lever against the horse's radius to stress the medial aspect. In young horses affected by carpalitis, this maneuver frequently elicits pain.

DIAGNOSTIC ANALGESIA

Diagnostic analgesia can be performed in sequence from distal to proximal, or, to save time, selective analgesic techniques can be used. For example, European trotters with a positive response to forelimb lower limb flexion inconsistently respond to palmar digital analgesia; therefore analgesia of the metacarpophalangeal or DIP joints may be the first option. Perineural analgesia is preferred, however, to avoid minor risks of joint infections or to save the opportunity to provide intraarticular therapy immediately (when working in stables, trainers frequently are interested more in treatment than in diagnosis). I frequently start with low plantar analgesia in the hindlimbs because lameness of the digit is rare. In young STBs with forelimb lameness and a positive response to carpal flexion, I block the middle carpal joint first.

In horses with obscure lameness or when lameness is only apparent during fast exercise, examining the horse on the track may be useful. The horse is rigged in full harness and first examined trotting in a clockwise direction. Speed then is increased, and the horse is turned to train in a counterclockwise direction, the same as racing. Clinicians can drive the horse themselves, sit in a two-seat wagon, or observe the horse from a car or from a distance. In my opinion, watching the horse during exercise is important, especially when routine training and racing can be simulated, and I prefer the horse to be driven by its usual trainer. Having the horse fully equipped, mimicking the stress of racing, and observing the horse in turns are important advantages to this form of lameness examination.

Diagnostic analgesia is useful, but the clinician must be aware of related risks and make the trainer and owner aware as well. Diagnostic blocks should be avoided in horses suspected of having incomplete fractures. Radiographic examination should precede diagnostic analgesia

in these horses. When examining a horse on the track after local analgesia, the trainer should be told to limit the speed as much as possible, avoiding any sudden stop or sharp turn. An experienced trainer normally is able to appreciate the benefits of a block quickly and without stressing the horse. Examination at speed is needed to make a diagnosis in horses with plantar process osteochondrosis fragmentation of the proximal phalanx and fragmentation of the distal border of the distal phalanx.

DIAGNOSTIC IMAGING

Sophisticated equipment for diagnostic imaging is now available in most European equine clinics. Scintigraphy is available in Europe but is limited to large referral hospitals. Radiography remains the mainstay of equine diagnostic imaging, and the availability of excellent portable units has improved the radiographic examination under field conditions. Digital radiography offers advantages in terms of imaging processing, time saving, radiation protection, and easier image storage. Ultrasonographic examination is commonly performed.

Common pathological findings in the distal limb of European trotters include osteophyte formation on the distal aspect of the middle phalanx, sometimes associated with modeling of the extensor process of the distal phalanx, as seen on a lateromedial image of the foot ([Figure 109-1](#)). This radiological pattern often is associated with heel growth proceeding faster than toe growth (club foot). When associated with a positive lower limb flexion test and lameness abolished using analgesia of the DIP joint, this radiological finding is important and indicates the presence of OA. Fragmentation of the extensor process of the distal phalanx has controversial clinical significance, but in my experience these fragments cause synovitis of the DIP joint and should be removed using arthroscopy.

The dorsoproximal-palmarodistal oblique radiographic image of the distal phalanx, unlike scintigraphy, rarely helps in diagnosing pain arising from stress remodeling of the distal phalanx; thus the diagnosis of pedal osteitis is

Fig. 109-1 • Lateromedial radiographic image of the distal interphalangeal joint of a Standardbred trotter. Osteophyte formation on the distal border of the middle phalanx associated with moderate remodeling of the extensor process of the distal phalanx (arrows) is a common pathological finding in European trotters.

Fig. 109-2 • Dorsoproximal 45-degrees medial-plantarodistolateral oblique radiographic image of a hind fetlock of a 2-year-old Standardbred. There is plantar fragmentation (*arrow*) of the proximal medial aspect of the proximal phalanx.

limited to horses with chronic lameness characterized by substantial radiolucency.⁴ Fragmentation of the lateral and medial palmar processes of the distal phalanx, although controversial as a cause of acute lameness, may be an important source of pain best managed by shoeing.

The flexed lateromedial image of the metacarpophalangeal or metatarsophalangeal joints is useful in evaluating lesions of the distal aspect of the McIII or the MtIII. In the hindlimb, the oblique images must be acquired in a proximal to distal direction (down-angled) to see better the area between the proximal phalanx and the base of the PSBs. Fragmentation of the proximal plantar aspect of the proximal phalanx represents a major cause of subtle hindlimb lameness (*Figure 109-2*).

A dorsopalmar image of the carpus helps to evaluate the proximal suspensory origin from the McIII, and focal or diffuse increased radiopacity of the McIII may be found (*Figure 109-3*). In yearlings and young horses, this image allows examination of the distal radius, and pathological modifications of the growth plate on the medial side (phy-sitis) are a frequent cause of early lameness. The most common lesions of the carpus are seen with the dorsolateral-palmaromedial oblique image and the dorsal 35° proximal-dorsal distal oblique (skyline) image of the flexed carpus to highlight the distal row of carpal bones. The radiographs must be of excellent quality, and the appropriate projection must be obtained because false-negative radiographic images are frequent. Abnormal findings include areas of radiolucency in the dorsoproximal articular border of the radial fossa of the third carpal bone, radiolucent lines suggestive of fractures, and increased radiopacity of the third carpal bone.⁵ A moderate degree of increased radiopacity in the radial fossa of the third carpal bone is considered normal in racing horses, but more severe increased

Fig. 109-3 • Dorsopalmar radiographic image of the proximal metacarpal region of a Standardbred trotter (lateral is to the left). Increased radiopacity of the palmar cortex of the proximal aspect of the third metacarpal bone (*arrows*) is a common finding in trotters with chronic proximal suspensory desmitis.

radiopacity associated with radiolucent areas represents a pathological finding.^{6,7}

In the hindlimb the centrodistal and tarsometatarsal joints frequently appear normal radiologically even when distal hock joint pain is diagnosed clinically as the source of pain. Scintigraphy is an excellent tool for diagnosing OA of these joints.⁸ The tarsocrural joint is a predilection site for OC in STBs, and the presence of fragments associated with effusion may represent an indication for arthroscopic surgery. Lesions affecting the lateral trochlear ridge of the talus and medial malleolus of the tibia more frequently cause lameness and effusion than do those of the cranial aspect of the intermediate ridge of the tibia. In horses with effusion but without obvious fragmentation, a specific dorsal 10° to 15° lateral-plantaromedial oblique image is required to evaluate the axial aspect of the medial malleolus. Subtle osteochondral fragmentation or radiolucency easily can be overlooked (*Figure 109-4*).

Curb is not seen frequently but can develop in the early stages of training in young horses. Curbs represent thickening of the plantar aspect of the hock and must be differentiated from the soft swelling caused by distention of a tarsal sheath. Abnormal stress to the plantar soft tissue structures can be predisposed by sickle-hocked or cow-hocked conformation. Accurate palpation differentiates curb from tarsal tenosynovitis. Ultrasonographic evaluation helps characterize the soft tissue structures involved in curb and assess severity (see Chapter 78). In the European STB, curb nearly invariably represents inflammation and thickening of the long plantar ligament, but ultrasonographic evaluation is necessary to differentiate long plantar desmitis from other soft tissue injury.

Trainers frequently ask for radiography or ultrasonography of the stifle because they seem to incriminate this

Fig. 109-4 • Dorsal 15° lateral-plantaromedial oblique radiographic image of the hock of a 2-year-old Standardbred colt. There is axial fragmentation of the medial malleolus of the tibia (arrows), which is difficult to detect unless oblique images are obtained. The condition can cause effusion of the tarsocrural joint and lameness.

joint as the source of pain causing lameness in horses with obscure hindlimb lameness. Radiography of the stifle is important in foals and yearlings with femoropatellar effusion. Lateromedial and caudocranial images must be obtained. OCD of the lateral trochlear ridge and, less frequently, subchondral bone cysts of the medial femoral condyle can cause effusion and lameness in young STBs. Ultrasonographic evaluation of the stifle is useful in detecting soft tissue injuries, but these lesions are rare in STBs. Mild dimples or cartilaginous defects on the articular surface of the medial femoral condyle can be detected using ultrasonographic examination by holding the stifle in a semiflexed (90 degrees) position.

FINAL DIAGNOSIS, PROGNOSIS, AND TREATMENT OPTIONS

A final diagnosis is made easily when the horse has obvious severe lameness, as is the case in horses with the more common fractures and tendon or ligament injuries (incomplete sagittal fracture of the proximal phalanx, PSB fracture, carpal chip or slab fractures, SDF tendonitis, and acute suspensory desmitis). Surgery or rest most often is recommended for these horses. In some horses, rest is the best option, and accurate monitoring of the healing process must follow (fracture of the distal phalanx, stress fractures of the proximal aspect of the McIII, and proximal suspensory desmitis [PSD]).

OA of the DIP joint, the metacarpophalangeal or metatarsophalangeal joints, or the middle carpal joint (particularly in young horses) can cause chronic lameness. Racetrack clinicians frequently inject the tarsometatarsal (TMT), centrodistal, and tarsocrural joints, but the true prevalence of problems arising from these joints has not been substantiated using diagnostic analgesia. Problems affecting the

proximal aspect of the hindlimb, in the absence of visible lameness, frequently are diagnosed, but definitive diagnosis is difficult to substantiate.

Intraarticular therapy includes corticosteroids or non-steroidal antiinflammatory drugs (NSAIDs) and, more recently, interleukin-1 receptor antagonist protein (IRAP). A series of four intraarticular injections of polysulfated glycosaminoglycans (PSGAGs), 250 mg every fourth day and then at weekly intervals, is helpful to treat juvenile OA, especially in the carpus. PSGAGs also have been useful parenterally (500 mg every 4 days for seven treatments).⁹ High-molecular-weight hyaluronan (20 to 40 mg) may be used alone or with corticosteroids. Hyaluronan (20 to 40 mg) may be used intravenously.¹⁰ The most popular corticosteroids for intraarticular therapy in horses include methylprednisolone acetate (40 to 60 mg), betamethasone disodium phosphate or betamethasone acetate (3 to 9 mg), and triamcinolone acetonide (6 mg). A basic treatment includes three intraarticular injections using 60 mg of methylprednisolone acetate for the first injection, followed by two injections of 40 mg at 2-week intervals. A similar protocol may be applied to betamethasone disodium phosphate and betamethasone acetate (6 to 9 mg the first time followed by two injections of 6 mg each). This treatment is usually helpful in horses with chronic OA of the DIP joint, the metacarpophalangeal or metatarsophalangeal joints, and the distal tarsal joints and sometimes resolves acute synovitis in young horses. When using triamcinolone acetonide (6 mg), clinicians must be aware of systemic effects and problems (laminitis and rhabdomyolysis) if several joints are injected at the same time. Although the cause is unsubstantiated, these complications may develop because of iatrogenic hyperadrenocorticism. Corticosteroids must be used in compliance with doping regulations.

Liniments, paints, and blisters are still popular, and despite lack of scientific support, they appear strongly tested by time. Iodide-based light paints diluted in dimethyl sulfoxide may be helpful in improving circulation to the distal aspect of the limbs and help to remove edema. Stronger blisters (with iodide mercury, cantharis, cedar oil, or turpentine) may play a role in improving circulation in some areas, but trainers must be made aware of possible secondary effects of the chemical-induced inflammation (scars, adhesions, cellulitis, and excessive joint inflammation) and that using most irritant blisters is no longer justified. Thermocautery (pin firing) is now less popular in Europe but is still used to treat STBs with curbs and proximal splint exostoses. Paints and blisters are used more frequently in France and Italy than in northern Europe.

CORRECTIVE SHOEING

Corrective shoeing is important for many STBs with forelimb lameness conditions. Generally speaking, a good lateral-to-medial balance and an ideal dorsal hoof wall angle must be provided before any shoe is applied. Then a large-based (wide-web) shoe is ideal but not always possible because of gait characteristics. Many trainers prefer thinner and lighter shoes because they are associated with increased speed. In horses with a flat sole the shoe must be in contact only with the wall border, and any rubber, leather, or silicon pad must be avoided. In these horses a

rigid (aluminum) sole may prove helpful, but frequent cleaning is required to avoid sand accumulation under the sole. In horses with OA of the metacarpophalangeal or metatarsophalangeal joints, bar shoes must be avoided because the bar prevents the natural slipping of the foot when landing and increases stress on these joints. A bar shoe may prove helpful in horses with SDF tendonitis, but I prefer to leave this shoe on only during the recovery phase and during light training, whereas an open shoe is preferred for fast training and racing.

TRAINING PROGRAMS

Alternative training programs can be a valuable adjunct therapy, especially when dealing with unnatural fast-gaited trotters. Clockwise jogging and training, training on straight tracks (using interval training schedules), and swimming are preferred. Training programs aimed at reducing speed and stress on the large upper limb muscles, such as fast trotting in a circle in deep sand and use of heavy wagons or wagons with preselected brake sets (power carts), have been used, but scientific studies and objective data to support use of these alternatives are lacking.

PROCEEDING WITHOUT A DIAGNOSIS

Progress in diagnostic imaging has made the situation rare in which a clinician cannot determine a diagnosis. When available, whole body scintigraphic examination in horses with occult lameness is useful. Results of scintigraphy must not be overinterpreted, and clinicians must be aware that conditions may be subtle or difficult to detect. Bone remodeling around OCD or osseous cystlike lesions may be subtle. When detailed clinical examination has failed to reveal a diagnosis, I suggest the following options:

1. The horse should be reassessed 10 to 15 days later. This may help in horses with acute lesions without initial radiological abnormalities and when scintigraphy is not available.
2. A second opinion can be considered, especially if the horse can be referred to a center that is equipped with advanced imaging equipment.
3. The horse should be treated with NSAIDs (phenylbutazone 2.2 mg/kg/day orally [PO] for 5 days and then every second day for 10 days) and then reevaluated.
4. The clinician should treat the most likely site or sites of pain with short-acting corticosteroids. Some trainers prefer this approach because they believe the horse does not lose time and often believe something has been done. In some horses, experienced horsemen may help the clinician effectively by asking for a specific therapy that may help the situation.
5. The clinician should give the horse a period of controlled exercise or rest. This decision is particularly helpful when dealing with young horses, in which early training may have promoted bone and soft tissue maladaptation and remodeling that requires time to heal. Before resting the horse, a complete radiographic examination is a good idea because horses with advanced disease may have a poor prognosis or may require additional rest.

TEN MOST COMMON LAMENESS CONDITIONS

The following are the 10 most common lameness conditions:

1. Hoof or foot pain
2. Osteoarthritis of the distal interphalangeal joint
3. Osteoarthritis of the metacarpophalangeal joint
4. Lameness associated with middle carpal joint pain
5. Proximal palmar metacarpal pain including proximal suspensory desmitis
6. Sesamoiditis
7. Suspensory branch desmitis
8. Lameness of the metatarsophalangeal joint
9. Superficial digital flexor tendonitis
10. Osteochondrosis of the tarsocrural joint

LAMENESS IN THE EUROPEAN TROTTER

Hoof Pain

This nonspecific definition refers to a number of conditions, including what most clinicians and trainers call foot pain. Lameness varies, and the response to flexion may be equivocal. Negative flexion tests in a lame horse may suggest nonarticular hoof pain, and the same applies to horses in which the trainer's complaint is pain (with compromised gait) at the end of the race. Horses may break stride on the last turn or may get on a line in the straightaway.

A thorough examination of the feet, including hoof tester examination, is performed as previously described. A series of selective diagnostic analgesic procedures follows. Palmar digital analgesia commonly improves lameness by 75% to 90%. If a less than 50% response is obtained, palmar blocks at the base of the PSBs are performed. I avoid analgesia of the DIP joint because I may choose to medicate the joint. Recent evidence suggests analgesia of the DIP joint is not specific, and pain originating from the sole may be abolished.¹¹

Diagnostic imaging includes radiography and scintigraphy. Stress remodeling of the distal phalanx is a common finding in trained STBs. Radiographs are usually negative, although occasionally marginal changes of the distal phalanx are seen.

Management includes corrective shoeing, controlled exercise, DIP joint injections, and local application of iodide ointments or blisters. Temporary pain relief has been reported anecdotally after perineural injection of cobratoxin, alcohol, or other preparations and after percutaneous cryotherapy. There can be complications such as substantial local inflammation and abscess formation with perineural injections. Horses with mild lameness respond to corrective shoeing: rubber or leather soles may be added to wide-web shoes, or different types of rubber flaps may be used temporarily. Light training for 2 to 3 weeks is suggested, and the horse is best trained on a soft track or on a straight track if available. Swimming is a good alternative method of training.

Osteoarthritis of the Distal Interphalangeal Joint

History, character of the lameness, response to flexion tests, and shape of the hoof are points to consider when OA of the DIP joint is suspected. Horses can be lame or

reported to be intermittently lame. The tendency is for horses to develop OA of the DIP joint and club foot because the hoof growth in the heel region is faster than in the toe region. Evaluation and trimming of the hoof wall to lower the dorsal angle may help prevent this conformational change. Palpation of the area over the coronary band may elicit pain, especially medially where the condition must be distinguished from chronic collateral ligament strain of the DIP joint. Mild pain also may be detected by palpation of the proximal aspect of the SL in the forelimb and muscles of the back, two common compensatory lameness conditions. Diagnosis can be frustrating because horses are not always improved with DIP analgesia (this may suggest pain originating in the subchondral bone), and the gait may be abnormal because of other problems frequently secondary to pain originating from the DIP joint. An 80% to 90% positive response to perineural analgesia must be considered clinically relevant.

Lateromedial radiographs of the distal aspect of the limb frequently show a prominent osteophyte on the distal aspect of the middle phalanx, sometimes associated with secondary remodeling of the proximal aspect of the distal phalanx (see [Figure 109-1](#)). Fragmentation of the extensor process of the distal phalanx may also be observed, in which case the hoof wall frequently has a grossly triangular shape. OA of the DIP joint may be bilateral but is most commonly unilateral.

Suggested therapy includes intraarticular therapy with corticosteroids, PSGAGs, high-molecular-weight hyaluronan, or a combination of these drugs three times at 7-day intervals (14 days when using corticosteroids); IRAP therapy represents a new promising alternative. Corrective trimming to decrease excessive heel growth and maintaining the hoof angle at about 50 degrees appear important. Wide-web shoes distribute load on a large surface area, and when possible, a rubber or leather pad is needed. The shoe should have a rolled toe to ease breakover. A thick rubber pad (flap or flip-flop) is used sometimes to replace the classic shoe ([Figure 109-5](#)).

Fig. 109-5 • A flap or flip-flop shoe can be useful in trotters with foot pain.

Osteoarthritis of the Metacarpophalangeal Joint

OA of the metacarpophalangeal joint may be acute or chronic. Acute synovitis is seen in young horses when training is intensified or when the track surface changes. Clinical signs include mild to moderate lameness, pain on palpation, and lameness after flexion. Radiographs are usually negative in young horses, but flattening or more severe changes of the sagittal ridge of the McIII in older horses with chronic OA often are seen. Contrast radiology reveals a filling defect corresponding to a hypertrophic synovial pad of the distal, dorsal aspect of the McIII. Ultrasonographic examination reveals various degrees of dorsal joint capsule thickening and increase in echogenicity of the synovial pad. Intraarticular analgesia abolishes the lameness in most horses.

In horses with acute synovitis, training program modulation (2 to 3 weeks of light jogging), corrective shoeing (wide-based shoes and pads), and intraarticular corticosteroids (a series of three injections at 2-week intervals) may resolve the problem. In these horses, concurrent pathological conditions of the articular cartilage, subchondral bone, and the synovial pad usually are lacking or mild. Horses with hypertrophic synovial pads benefit from arthroscopic surgery to remove the thickened tissues because response to medical management is poor. This is frequently the case in older horses, in which advanced OA is often present. Prognosis after surgery is only fair to guarded, however.

Middle Carpal Joint

The middle carpal joint is the most common site of lameness in young STBs. Typically, affected horses tend to trot with a wide gait, abducting the affected limb or limbs in an attempt to minimize carpal flexion.¹² Visual inspection from a dorsolateral perspective reveals abnormal contour of the dorsomedial aspect of the carpus. Palpation often elicits a painful response over the dorsal aspect of the radial and third carpal bones. Usually the response to carpal flexion is positive, and intraarticular analgesia abolishes lameness in most horses. A negative result from intraarticular analgesia does not rule out the middle carpal joint as the source of pain causing lameness because subchondral bone damage under a relatively normal cartilage layer may cause pain that may not be desensitized completely. Radiographs are usually diagnostic, especially the skyline image of the distal row of carpal bones. Abnormal radiological findings range from complete slab fracture of the third carpal bone to more subtle signs of radiolucency of the radial fossa of the third carpal bone. Scintigraphy is a sensitive and excellent tool in the early diagnosis of middle carpal joint injury.⁸

Training program modulation and intraarticular injections of PSGAGs, hyaluronan, or small amounts of corticosteroids are the first steps in the treatment program. Arthroscopy is suggested when evidence of more severe bone damage exists. Chip fractures in STBs most frequently involve the third and radial carpal bones. Counterclockwise racing, especially in the turns, concentrates forces along the medial aspect of the right forelimb, and this makes the right middle carpal joint more predisposed to injuries.¹³⁻¹⁵ The proximal border of the third carpal bone is involved more frequently than the distal border of the radial carpal bone in the STB trotter, unlike in the Thoroughbred (TB) and in the pacer.^{13,15,16} Arthroscopic surgery

and rest generally yield a fair to good prognosis.¹⁵ STBs with incomplete slab fractures of the third carpal bone may heal with rest, possibly preceded by diagnostic arthroscopy and curettage of the lesion. Horses with complete slab fractures are best treated by internal fixation. Thin fragments are removed. When arthroscopy shows substantial loss of articular cartilage, the micropick technique may increase the possibilities of cartilage repair.¹⁷ Arthroscopic findings in young STBs have been shown to correlate poorly with radiological findings, and lesions appear frequently more severe than expected.¹⁶ In horses without radiological changes, I frequently find depressions and discoloration of articular cartilage (especially in the radial fossa of the third carpal bone), loss of articular cartilage in focal areas of the third and radial carpal bones, and partial or complete tearing of the medial palmar intercarpal ligament. Ligament injuries, especially affecting the medial palmar intercarpal ligament, must be suspected in the absence of radiological abnormalities.¹⁸ However, medial palmar intercarpal ligament injuries are rare. These horses are treated using arthroscopic trimming and are given 4 to 6 weeks of stall rest followed by 4 weeks of stall rest with handwalking exercise, and joints are injected with short-acting corticosteroids.

Proximal Palmar Metacarpal Pain Including Proximal Suspensory Desmitis

Proximal palmar metacarpal pain affects many more horses than we once thought. Mild pain in the proximal palmar aspect of the metacarpal region may be secondary to other gait disturbances and may reflect attempts to maintain balance when trotting fast. In these horses the lesion rarely is substantiated by ultrasonography, but pain may be detected with accurate palpation (racetrack clinicians used to diagnose and treat “blind splints” in this area).

PSD is usually acute in onset, and direct palpation of the SL elicits pain. A carpal flexion test is often positive. Intraarticular analgesia of the middle carpal joint produces a variable amount of improvement, but some degree of lameness still is elicited by flexion. Subcarpal analgesia (4 mg of local anesthetic solution placed axial to each of the second and fourth metacarpal bones or direct infiltration of 2% mepivacaine over the proximal aspect of the SL) usually abolishes lameness.

Diagnostic imaging includes radiography, scintigraphy, and ultrasonography. Scintigraphy is useful in identifying horses with bony injury, including horses with an avulsion fracture of the McIII at the origin of the SL, those with enthesopathy, or those with a longitudinal fracture of the McIII. Horses with PSD without bony involvement may have positive pool phase images, but delayed images are usually negative. Radiography (dorsopalmar and flexed lateromedial images) may reveal associated longitudinal or avulsion fractures of the proximal, palmar aspect of the McIII or, in horses with chronic lameness, increased radiopacity of the McIII at the SL origin (see [Figure 109-3](#)). Ultrasonography is useful in identifying patterns of ligamentous injury, palmar cortical bone damage, and monitoring the healing process.

The prognosis is fair to good, provided the affected horse is subjected to walking exercise and controlled training with concurrent monitoring of the healing process. STBs may tolerate an acceptable level of training with

chronic injuries of the SL compared with TBs, possibly because of the increased percentage of muscle fibers present in the SL.¹⁹ The prognosis in horses with PSD is better than those affected with lesions in the suspensory body.

Therapy includes 6 to 8 weeks of rest followed by 4 to 6 weeks of 20 to 60 minutes of walking exercise or swimming. Local application of blisters and injections of corticosteroids or PSGAGs may help but rarely shorten the healing period. Cryotherapy has gained some popularity in treating STBs with PSD in racetrack practice, but its usefulness has not been substantiated scientifically. Several biological therapies have gained recent acceptance: intralesional injection of bone marrow,²⁰ isolated or cultured stem cells, and platelet-rich plasma (PRP). However, more research and clinical work are required to substantiate their value. Shock wave therapy also has been used to treat horses with PSD in recent years (see Chapter 96).

Sesamoiditis

Sesamoiditis may be defined as enthesopathy at the insertion of the branches of the SL to the abaxial surface of the PSBs. The condition also may affect the base of PSBs, but this form is rare and is best defined as distal sesamoidean desmitis. Two types of sesamoiditis are recognized. Type 1, or juvenile sesamoiditis, is characterized by radiolucent lines (vascular channels) in the proximal third of a PSB, radially oriented as seen in lateromedial or oblique radiographic images, and is a frequent feature in young (2- and 3-year-old) STBs ([Figure 109-6](#)). This radiological pattern is not always associated with lameness, and no link has been observed between the presence of these lines and PSB fractures.²¹ Affected horses tend to be lame after training, but pain subsides with rest. Intraarticular analgesia does not abolish lameness. Lameness disappears after perineural analgesia of the medial and lateral plantar (palmar) nerves. The condition usually involves one or both hindlimbs, and the lateral PSB is affected more frequently. Scintigraphic examination reveals increased radiopharmaceutical uptake (IRU), but radiological changes are seen in only 50% of STBs with scintigraphic abnormalities.⁸ The lateral PSB

Fig. 109-6 • Dorsolateral-plantaromedial oblique radiographic image of a metatarsophalangeal joint of a lame 2-year-old Standardbred colt with juvenile sesamoiditis. Note the radiolucent lines in the lateral proximal sesamoid bone.

represents one of the most frequent locations for IRU in racing STBs.^{8,22}

Type 2 sesamoiditis is chronic, frequently affects a single PSB, and is found more commonly in the forelimbs of older horses. Radiological signs of type 2 sesamoiditis (evidence of radiolucent lines in the proximal half of the bone, irregular palmar/plantar and abaxial outline of the bone, enthesophytes, and mineralization of the adjacent interesesamoidean ligament) are associated with ultrasonographic evidence of suspensory insertion desmitis. One or both suspensory branches often are involved. Focal loss of echogenicity in horses with acute disease and increased echogenicity in horses with chronic lameness are common abnormal ultrasonographic findings. The insertion on the PSB (enthesis) becomes grossly irregular.

In horses with type 1 sesamoiditis, treatment involves rest, slow training, or turnout for 30 to 90 days, depending on the degree of lameness present. Radiological monitoring of the lesion is probably not helpful because lameness may improve substantially despite the persistence of radiolucent lines. More information is provided by scintigraphy initially and during follow-up examination. Medical treatment includes local application of paints or mild blisters and corrective shoeing (bars must be avoided; the quarters must be lowered moderately; and shoes must provide a wide base in the hindlimbs). Medical treatment is aimed at improving local blood flow, and isoxsuprine hydrochloride (0.6 to 1.2 mg/kg PO twice daily) and sodium acetylsalicylate (10 mg/kg PO twice daily) are recommended for 45 to 60 days. The efficacy of this therapy, however, is questionable. The prognosis is fair if lameness is not severe and if the horse tends to warm out of lameness. If severe lameness is observed and associated radiological changes are pronounced, the prognosis is guarded. These horses are best given long periods of rest and paddock turnout (6 to 8 months). Treatment of horses with type 2 sesamoiditis includes rest, corrective shoeing (wide-web aluminum shoes, leather pad, with particular attention to lateral-to-medial hoof balance), local application of dimethyl sulfoxide, and paints and blisters. Pin firing is no longer justified. Cryotherapy has become popular in recent years, but in my opinion its clinical efficacy is poor. The prognosis is fair, but hoof balance must be monitored to prevent recurrence. Low-level or alternative (swimming) training is indicated.

Suspensory Branch Desmitis

Suspensory branch desmitis can be acute or chronic and is caused by lateral-to-medial hoof imbalance, exercise over uneven track surfaces, strains, and chronic fractures of the second and fourth metacarpal/metatarsal (splint) bones. Acute desmitis can be associated with metacarpophalangeal/metatarsophalangeal joint effusion. Shoeing changes, particularly when the hoof angle is modified (usually increased), frequently precede the condition, and when treating the condition, hoof imbalances must be identified and corrected. Ideally the dorsal hoof angle in the forelimb should be kept between 48 and 52 degrees, with a shoe providing good support to the heel. The routine training regimen, track conditions, and the counterclockwise direction of racing may affect the distribution of suspensory branch desmitis. In my experience the right forelimb and right hindlimb are most commonly affected, and lesions of the medial branch are twice as common as those of the

lateral branch. Radiography and ultrasonography are performed to assess ligament damage and bone involvement. Enlargement and loss of definition of the margins of the branch, focal hypoechogenic areas, or diffuse loss of echogenicity and hyperechogenic foci in horses with chronic desmitis are the most frequent ultrasonographic findings.²³ Radiologically the ipsilateral splint bone may appear deviated abaxially, and in horses with chronic lameness, adhesions may develop between the splint bone and suspensory branch, causing fracture during fast exercise. For the latter reason, radiological monitoring of the splint bones is suggested in horses with chronic desmitis. The insertion of the branch on the PSB must be assessed by ultrasonography for the presence of insertional desmitis.

The treatment in horses with acute desmitis includes rest, antiinflammatory drugs (phenylbutazone 2.2 mg/kg), or local application of dimethyl sulfoxide and poultices. Intraarticular injection of corticosteroids may be beneficial when the condition is associated with metacarpophalangeal/metatarsophalangeal joint effusion. In horses with chronic or severe desmitis, rest and local application of mild blisters may help. Fast training must be avoided when possible, and corrective shoeing must be provided. Alternative training programs, especially swimming physiotherapy, are indicated and can allow an acceptable level of exercise without worsening the lesion.

Metatarsophalangeal Joint

The metatarsophalangeal joint represents a major source of hindlimb lameness in STBs.²⁴ Lameness of the metatarsophalangeal joint and specifically the plantar aspect is frequently subtle, and diagnosis can be challenging. Mal- or nonadaptive modeling of the plantar aspect of the metatarsophalangeal joint, proximal plantar fragmentation of the proximal phalanx, and nonunion of the lateral eminence of the proximal phalanx represent the most common conditions. Traumatic OC of the distal plantar aspect of the condyles of the MtIII and mineralization of the distal sesamoidean ligaments are observed rarely.

Subchondral nonadaptive remodeling of the MtIII has been described and represents a scintigraphic finding, with a corresponding radiological pattern not easily identifiable (Figure 109-7).²² Proximal plantar fragmentation of the proximal phalanx has been reported by several authors in radiological surveys of young STBs and is commonly seen (see Figure 109-2).^{25,26} Plantar fragments from the proximal phalanx rarely are associated with lameness at a trot in hand. Trainers' complaints include gait disturbances during fast exercise, especially in turns, and the tendency for the horse to be on one shaft. Intraarticular analgesia of the metatarsophalangeal joint can alleviate lameness, but a fast exercise test is required, and owners must be aware of the potential consequences of this procedure. For this reason, when the clinical pattern indicates pain arising from the metatarsophalangeal joint, a radiographic examination including the oblique images (dorsoproximolateral-plantarodistomedial oblique and dorsoproximomedial-plantarodistolateral oblique) is required. In horses with plantar process OC fragments, arthroscopic surgical removal of fragments is indicated. The prognosis after surgical treatment is good. In horses with nonadaptive remodeling of the distal aspect of the MtIII, rest or reduced training, intraarticular injections of PSGAGs, or low doses of corticosteroids and hyaluronan are recommended.

Fig. 109-7 • A radiolucent defect (arrow) in the distal, plantarolateral aspect of the third metatarsal bone is visible on the dorsal 45° lateral 30° proximal-palmarodistal oblique radiographic image, the result of stress or nonadaptive remodeling.

Superficial Digital Flexor Tendonitis

The incidence and morbidity of STBs with SDF tendonitis are lower compared with TBs, but tendonitis of the superficial digital flexor tendon (SDFT) and suspensory desmitis represent the main indications for ultrasonographic examination of the distal aspect of the forelimbs in STB racehorses in Europe.

In my experience, most of the lesions are located in the middle and distal thirds of the SDFT. A core lesion located in the palmarolateral border of the tendon characterizes more than 30% of the lesions identified using ultrasonography. More rarely central core lesions are seen. Horses with chronic lesions have the typical pattern of diffuse tendonitis. Therapy includes rest; corrective shoeing; local application of antiinflammatory ointments, poultices, dimethyl sulfoxide, paints, or blisters; tendon splitting; desmotomy of the accessory ligament of the SDFT; and desmotomy of the palmar annular ligament. Intralesional injections of hyaluronan or PSGAGs have been reported. Promising results after bone marrow, cultured stem cell, and PRP therapy have been reported anecdotally. My treatment of choice in horses with acute lameness includes corrective shoeing (moderate lowering of the heels, correcting lateral-to-medial balance, and using wide-based shoes without pads, especially rubber pads), local application of dimethyl sulfoxide, cold water therapy twice a day, poultice application, and walking exercise for 2 to 4 weeks. The initial treatment is followed by the local application of an iodine blister, and the horse is given an additional 4 to 8 weeks of walking exercise. The horse usually is able then to resume jogging unless lameness is present. Ultrasonographic examination is performed 12 weeks later.

In horses with recurrent tendonitis, my treatment of choice includes desmotomy of the accessory ligament of the SDFT (superior check desmotomy). Desmotomy of the palmar annular ligament also is performed when substantial tendonitis involving the distal aspect of the tendon or digital flexor tendon sheath effusion is present. After

surgery, horses are given 2 weeks of box stall rest, followed by 8 weeks of walking exercise.

Tendonitis of the SDFT within the pastern region is less common but more difficult to manage than tendonitis in the metacarpal region. Lameness is more pronounced, and recurrence of clinical signs is common. With ultrasonography, lesions can be detected at the tendon insertion over the lateral or medial aspect of the middle phalanx. Treatment includes rest, local and systemic antiinflammatory drugs, blisters, corrective shoeing, and alternative training, particularly swimming. Monitoring of the healing process is important to prevent recurrence.

Osteochondrosis of the Tarsocrural Joint

Joint effusion represents the most common feature of tarsocrural OC, a condition with a reported prevalence ranging between 4% and 20%.²⁵⁻³³ Tarsocrural OC frequently is diagnosed in yearlings, and breeders are particularly concerned because the condition may lower the yearling's price at the autumn sales. For this reason, tarsocrural effusion in yearlings now represents a frequent indication for radiographic examination and preventative arthroscopy.

Lameness associated with OC is rare, but selected lesions may cause gait disturbances. In horses with effusion and osteochondral fragmentation, it is important to rule out other causes of lameness. Lesions affecting the lateral trochlear ridge of the talus and medial malleolus of the tibia are more likely to cause lameness and synovial effusion than are lesions of the cranial aspect of the intermediate ridge of the tibia. Focal areas of radiolucency or loss of radiopacity on the medial malleolus may be associated with osteochondral fragmentation and may represent an indication for diagnostic arthroscopy.³⁴ In young horses with effusion, arthroscopic removal of fragment(s) represents the best option. Prognosis after arthroscopic treatment of tarsocrural OC is good, but synovial effusion may persist especially when OC involves the lateral trochlear ridge of the talus and the medial malleolus.^{35,36} Studies performed in Europe found no significant differences in the racing performance and longevity of STB trotters with or without tarsocrural OC.^{1,32,37}

THE AUSTRALASIAN STANDARDBRED

R. Chris Whitton

DESCRIPTION OF THE SPORT

Standardbred (STB) horses have been racing in Australia and New Zealand for more than 140 years. In both countries the sport does not enjoy the same high profile as Thoroughbred (TB) racing, and prize money is generally lower, which attracts fewer professional trainers than TB racing. Owner/trainers are common, with many stables having fewer than 10 horses. Horses can begin racing at 2 years of age and generally race until 8 or 9 years of age.

Most races are for pacers, with trotting races being much less common. In Australia, races range in distance from 1600 to 2600 m, and most pacing races are from a mobile start, with an occasional standing start. All trotting races are from a standing start. In New Zealand, races tend

to be longer, up to 3200 m, and standing starts are more common.

Regional meetings carry prize money of \$A2000 (Australian dollars) to \$A5000 per race, whereas metropolitan meetings offer \$A15,000 per race. The 15 most valuable pacing races in Australia and New Zealand make up what is called the Grand Circuit. Prize money for Grand Circuit races ranges from \$A125,000 to \$A1,000,000 for the Interdominion Pacing Championship Final and the New Zealand Cup. Prize money for trotting races is substantially less than that for pacers. The Interdominion trotter's Championship Final carries a \$A250,000 prize, and New Zealand's Row Cup has a prize of \$NZ300,000.

An increased number of stakes programs for young horses have become available in recent years. The Australasian Breeders Crown is held over all states of Australia and both islands of New Zealand for 2-, 3-, and 4-year-old pacers and trotters. Australian Pacing Gold is a program for yearlings sold at the sales of the same name and also has feature races for 2-, 3-, and 4-year-olds. The value of these programs puts great pressure on trainers and clinicians to persist with young horses that may benefit from rest.

Race speeds generally are expressed as mile rates, which is the time taken to travel 1 mile averaged over the whole race. Tight tracks result in slightly slower rates than large tracks. Typical mile rates for pacers in 1600-m races are 1:56 to 1:58. For 2400-m races, mile rates of 2 minutes are typical.

TRACK SURFACE OR TRAINING SURFACE AND LAMENESS

Most of the racetracks are 700 to 1000 m in circumference, and races are run in a counterclockwise direction, except for the north island of New Zealand, where races are run clockwise. Track surfaces vary but usually consist of sand or fine gravel. Banking of turns tends to be modest, although a trend to greater degrees of banking and resulting reduced injury rates has been demonstrated. Many trainers have their own homemade training track that is often just graded dirt or sand and not always well maintained, and recurrent subsolar bruising can be a major problem. Banking on these tracks tends to be minimal. In coastal areas, training on the beach is popular and considered beneficial for horses with injuries.

TRAINING METHODS

A typical training program involves a period of jogging exercise, generally of about 6 weeks, and these sessions generally last 35 to 40 minutes. Higher-speed work in hobbles (pace work) is introduced two to three times a week. A typical workout is two intervals of half to three-quarter pace over 1½ miles. The speed of these workouts is steadily increased over 4 to 6 weeks until speeds approaching those of race speed are achieved. A horse that is racing generally is hobbled twice a week and jogged on the other days. Training in New Zealand is similar, with the major difference being the tendency to house horses in paddocks rather than in stables.

LAMENESS EXAMINATION

Experience in examining STBs for lameness is essential because of their awkward gait, even when trotting. A high incidence of lameness occurs in horses in full work, and numerous sites of pain are common.

Examination at Rest (Preferably in a Stable)

The clinician should observe the horse standing for any obvious swelling, abnormal weight bearing, and areas of hair loss on the proximal limbs associated with the position of the hobbles. The clinician should palpate the neck and back to detect any areas of pain; palpate the supraspinous ligament, dorsal spinous processes, and dorsal sacroiliac ligament, along with the longissimus dorsi muscles; and then examine each limb in turn. Palpation is performed with the limb bearing weight and not bearing weight. The veterinarian should palpate the digital pulse amplitude in the distal aspect of the pastern or over the abaxial surface of the proximal sesamoid bones (PSBs). Observe each joint and palpate for swelling or effusion. Palpate the tendons and ligaments for heat, pain, and swelling. Particular attention should be paid to all levels of the suspensory ligaments (SLs) of the forelimbs and hindlimbs. The clinician should take time to examine the hind fetlock joints for effusion. Flex the joints firmly to detect pain, and apply hoof testers to each foot.

Trotting in a Straight Line

The horse should be trotted on a firm flat surface. Many horses pace initially, which makes the diagnosis of subtle lameness difficult. Persistence is important because most horses will trot after two or three runs up and down. The horse should be observed trotting away from and toward the observer and should be observed from the side.

Flexion Tests

Flexion tests have limitations but are a useful addition to the lameness examination. It is important to perform hindlimb fetlock flexion tests separately from proximal limb flexion tests because hindlimb fetlock problems are common.¹

DIAGNOSTIC ANALGESIA

Nerve blocks generally are required where no cause of lameness is obvious or the importance of a clinical finding is not clear. Where no localizing clinical signs are apparent, I use a standard approach: in the forelimb a pastern ring block is performed. The veterinarian should avoid nerve blocks at the level of the PSBs because distinguishing between PSB pain and foot pain is difficult. This is followed by a low four-point block and then a subcarpal block and intraarticular blocks of the middle carpal joint and then the antebrachiocarpal joint. Should the horse fail to respond to these blocks, median and ulnar nerve blocks are performed to rule out the lower limb as a source of pain. Rarely are blocks of the elbow joint, intertubercular (bicipital) bursa, or shoulder joint required.

A similar sequence of blocks is used in the hindlimb. A single lateral plantar metatarsal nerve block may be performed if plantar condylar subchondral bone pain is suspected. A subtarsal block is followed by an intraarticular

block of the tarsometatarsal joint and then the centrodistal joint. The tarsocrural joint is seldom blocked because there is generally swelling associated with intraarticular pathological conditions. Tibial and fibular blocks are performed to rule out the lower limb as the source of pain. Occasionally an intraarticular stifle block is required, in which case all compartments should be blocked at one time.

IMAGING CONSIDERATIONS

Radiography remains an important imaging technique. Oblique images of the distal phalanx are important when a fracture is suspected because some may be missed on dorsopalmar images. A flexed lateromedial image of the metacarpophalangeal joint should be obtained to highlight the sagittal ridge of the distal aspect of the third metacarpal bone (McIII) and the dorsal surfaces of the PSBs. Proximodistal oblique images of the hind fetlocks are obtained to demonstrate fragments of the proximal plantar aspect of the proximal phalanx and the lateral condyle of the third metatarsal bone (MtIII). Carpal images should always include a skyline image of the third carpal bone.

Ultrasonographic examination of the digital flexor tendons and SLs commonly is required. Superficial digital flexor tendon (SDFT) lesions are often peripheral rather than core lesions. Lesions also may involve the distal third of the metacarpal region or the proximal metatarsal region, areas that are examined less commonly by ultrasonography and may be more difficult to assess. Cross-sectional area measurements comparing affected and nonaffected limbs are essential when assessing subtle lesions. When examining the SLs, it is important to assess the full length because lesions can affect the origin, body, and branches.

Scintigraphy is useful for assessing STBs with complex lameness, STBs that fail to improve with diagnostic analgesia, and when pain is localized but no abnormalities are detected with radiography or ultrasonography. Stress fractures are common and can be insidious in onset. Typical sites include the third tarsal bone, lateral cortex of the tibial shaft, and the distal phalanges. Subchondral bone injuries may not be observed on radiographs yet are well documented with bone phase scintigraphic images.

PROCEEDING WITHOUT A DIAGNOSIS

Intraarticular corticosteroids often are used to assist in diagnosing subtle hindlimb lameness. Bilateral intraarticular injection of the tarsometatarsal and centrodistal joints may be used in horses in which hindlimb lameness is too subtle for accurate assessment by nerve blocks. Triamcinolone acetonide is the most commonly used intraarticular corticosteroid because of its relatively short and predictable detection time. Treatment of metatarsophalangeal joints also is often performed because lameness can be subtle. The clinical relevance of fragments of the plantar aspect of the proximal phalanx is often questionable, and intraarticular therapy may be the only method of confirming that metatarsophalangeal joint pain exists.

SHOEING CONSIDERATIONS

Most horses are shod and trimmed by the trainer or owner. Therefore the quality varies extremely. Steel rim shoes

generally are used, with trailers on the hind feet being universal. These shoes are thin and provide little protection for the sole. An occasional horse is trained and raced barefoot. Wider web aluminum shoes, similar to those used on TB racehorses, are available, but the use of these shoes is less common. These shoes generally have steel inserts to improve grip. Glue-on shoes rarely are used. In an attempt to promote increased length of stride, toes are often left overlong but there is no evidence to support this traditional approach. The combination of overlong toes and the lack of sole protection predisposes horses to subsolar bruising. Manipulation of shoeing methods is used for horses that hit the carpi during the swing phase. Generally this is trial and error. Heavier shoes tend to exaggerate any abnormal movement in the swing phase and result in higher hoof flight.

TEN MOST COMMON LAMENESS CONDITIONS

1. Subsolar bruising
2. Foot abscess
3. Osteoarthritis of the metacarpophalangeal or metatarsophalangeal joint and other conditions
4. Carpal joint disease
5. Suspensory desmitis
6. Superficial digital flexor tendonitis
7. Osteoarthritis of the distal tarsal joints
8. Fracture of the distal phalanx
9. Sagittal fracture of the proximal phalanx
10. Osteochondrosis of the tarsocrural joint

DIAGNOSIS AND MANAGEMENT OF LAMENESS

Subsolar Bruising and Abscessation

The diagnosis of subsolar bruising is based on pain with the application of hoof testers over the sole, either localized or generalized, and increased lameness after concussion of the foot. Lameness is localized to the foot with a pastern ring block, and radiography is performed to rule out a fracture of the distal phalanx. Chronic bruising may result in radiolucency and modeling of the margins of the distal phalanx, but these changes do not necessarily mean that the bruising is active. Scintigraphy will allow assessment of active inflammation and bone metabolism. Hemorrhage within the horn of the sole may or may not be evident. Horses with acute lameness are treated with rest and nonsteroidal antiinflammatory drugs. Careful attention should be paid to foot balance, and wide-web aluminum shoes should be fitted.

Osteoarthritis of the Fetlock Joint

Osteoarthritis (OA) of the metacarpophalangeal or metatarsophalangeal (fetlock) joint may or may not be associated with joint effusion and swelling. Usually the horse shows pain on passive flexion and a positive response to a fetlock flexion test. Lameness should be improved with a low four-point block or intraarticular analgesia. If lameness is recent, no radiological abnormalities will be apparent, but more chronic lameness is associated with modeling changes on the dorsal aspects of the proximal phalanx and the McIII or the MtIII. Modeling also may be observed on the articular margins of the PSBs and the palmar or plantar aspect of the proximal phalanx. In

advanced OA, subchondral radiolucent or cystic lesions may be observed in the palmar or plantar aspect of the condyles of the McIII or the MtIII. This is most common in the lateral condyle of the MtIII and is best observed on a proximodistal oblique radiographic image. Scintigraphy may be required for horses with few radiological changes and demonstrates increased radiopharmaceutical uptake in the subchondral bone.

Proliferative Synovitis

Proliferative synovitis occasionally causes lameness in STBs. Lameness generally is localized to the metacarpophalangeal joint by either perineural or intraarticular analgesia. Abnormal concavity proximal to the dorsal and occasionally the palmar aspects of the sagittal ridge of the McIII is observed on lateromedial radiographic images. Ultrasonography demonstrates enlargement of the synovial pad medial or lateral to the sagittal ridge of the McIII on the dorsal aspect, which must be differentiated from the joint capsule. Intraarticular corticosteroids may be used, but the results often are disappointing. Surgical excision of the synovial pad using arthroscopy is usually effective in resolving the lameness. The prognosis is poorer in horses with modeling of the palmar aspect of the McIII because this usually reflects the presence of more advanced chronic OA.

Axial, Articular (Type 1) Osteochondral Fragments of the Proximal Plantar Aspect of the Proximal Phalanx

Fragments of the proximal plantar aspect of the proximal phalanx are best observed on proximodistal oblique radiographic images of the metatarsophalangeal joints. These views should be included in the workup of horses with low-grade hindlimb lameness or a history of not running straight. Lameness is generally mild or not present at low speeds. Most horses have a positive flexion test of the affected fetlock, and about half have joint effusion.³ Osteochondral fragments of the proximal plantar aspect of the proximal phalanx are most commonly found medially but can occur laterally or biaxially. These fragments are present by 1 year of age and are thought by some to be traumatic in origin. Treatment involves arthroscopic removal, and treated horses can be returned to training within 6 weeks. Intraarticularly administered corticosteroids are sometimes used to determine the relevance of these lesions because not all are associated with poor performance.

Carpal Joint Disease

Lameness caused by carpal pain is common in Australasian STBs, affecting up to 30% of horses in training. In the absence of intraarticular fractures, lameness is often bilateral, and effusion is mild or absent. Because of the lack of localizing signs, intraarticular analgesia must be used to localize the pain causing lameness to the carpus. Radiographs should always include a skyline image of the third carpal bone. Often only increased radiopacity with or without focal radiolucent defects of the third carpal bone is observed.

Intraarticular fractures of the carpal bones generally involve the middle carpal joint. Fractures involving the antebrachio-carpal joint are less common and lameness is generally mild. More severe lameness is seen in horses

with slab fractures or severe joint injury. Joint swelling and pain on flexion are common. Treatment options include arthroscopic surgery to remove diseased bone and cartilage, intraarticularly administered corticosteroids, and rest.

Suspensory Desmitis

In most horses with suspensory desmitis, swelling and pain on palpation of the affected area of the SL are obvious, but lesions confined to the origin may be more difficult to diagnose, and subcarpal or subtarsal nerve blocks are required for diagnosis. Ultrasonographic examination confirms desmitis based on increased cross-sectional area and areas of decreased echogenicity. Radiological examination is used to assess the palmar or plantar aspect of the McIII or the MtIII and the PSBs at the proximal and distal attachments of the SL. The ideal treatment involves an initial period of rest and antiinflammatory treatment to allow the inflammation to resolve, followed by a period of controlled exercise. Horses should not return to full work for 12 months. In practice this is not always possible, and many horses can be managed by reducing the workload for shorter periods, treating with antiinflammatory drugs, and monitoring the response with ultrasonography.

Superficial Digital Flexor Tendonitis

Tendon injuries are easy to diagnose when the midmetacarpal or midmetatarsal area is involved. Swelling and pain on palpation are indications for ultrasonographic examination to confirm the diagnosis and differentiate from peritendinous inflammation. Horses with moderate to severe injuries are treated with rest and antiinflammatory therapy until the swelling is reduced, followed by a controlled exercise program. Intralesional injection of bone marrow or bone marrow-derived stem cells has been used, but long-term follow-up data on efficacy are currently lacking. Full work should not be reintroduced until 12 months after injury. Less severely injured horses may be kept in work, provided the exercise level is reduced and the tendon is monitored by ultrasonography. Such management is more successful in horses with hindlimb injuries. Tendon injuries at the level of the digital flexor tendon sheath (DFTS) may result in secondary palmar annular ligament (PAL) constriction and tenosynovitis. Lameness and effusion of the DFTS are observed when the horse is returned to training. Provided healing of the tendon injury is adequate, the PAL can be sectioned tenoscopically and the horse rapidly returned to training to prevent the formation of adhesions.

Osteoarthritis of the Distal Tarsal Joints

Confirmation of the distal tarsal joints as the source of pain causing lameness involves using intraarticular analgesia or intraarticular medication in horses with more subtle lameness. Although radiographs are useful for determining the extent of bony changes, they are not always diagnostic. Scintigraphy is more sensitive and may also reveal stress fractures of the third tarsal bone or the proximal dorsal aspect of the MtIII. Treatment involves intraarticular injection of long-acting corticosteroids. Triamcinolone acetonide is the most commonly used because of its reliable excretion times and reliable duration of action.

Fracture of the Distal Phalanx

STBs with a sudden onset of forelimb lameness after racing or fast work but with no localizing signs should be suspected of having a fracture of the distal phalanx. Application of hoof testers usually elicits pain, but this is not always consistent. Oblique radiographic images of the foot often are required to assess the fracture properly. It is important to determine whether the fracture enters the DIP joint. Most fractures are intraarticular. In horses that race counterclockwise, left forelimb fractures are generally of the lateral palmar process, and right forelimb fractures are generally of the medial palmar process. Occult fractures are occasionally identified with scintigraphy. Horses with nonarticular fractures are treated with a bar shoe with quarter clips or a rim shoe, and 12 months of rest. Horses with articular fractures may be treated in the same manner or by internal fixation with a single 4.5-mm screw placed in lag fashion along with a bar shoe with quarter clips. Evidence of the relative success of these treatments is limited, with the choice depending on individual preference. Reports indicate that 50% to 75% of Australian STBs with fracture of the distal phalanx are able to race following treatment with a bar shoe.² It is recommended that a bar shoe be maintained when horses return to racing to reduce the risk of refracture.

Sagittal Fracture of the Proximal Phalanx

The clinical presentation of horses with sagittal fractures of the proximal phalanx depends on fracture configuration. Horses with short, incomplete fractures may have chronic lameness that is localized to the fetlock joint with

nerve blocks. Longer fractures often cause acute onset of lameness. Swelling may be present, and the horse often has pain on palpation of the dorsal aspect of the proximal phalanx. Nerve blocks are contraindicated because of the risk of progression of the fracture. Radiological examination confirms the diagnosis. Horses with nondisplaced fractures may be treated with external coaptation. Internal fixation with screws placed in lag fashion is recommended for horses with complete and displaced fractures. Horses with short, incomplete fractures may heal with rest. Internal fixation has been recommended for horses with fractures that fail to heal.

Tarsocrural Osteochondrosis

The most common osteochondrosis lesion affecting the tarsocrural joint of STB horses involves the cranial aspect of the intermediate ridge of the tibia. Most horses have effusion of the tarsocrural joint, and lameness is absent or subtle. Radiographs demonstrate fragmentation of the cranial aspect of the intermediate ridge of the tibia. The fragments are removed arthroscopically.

Stifle Disease

Lameness localized to the stifle is rare in the STB racehorse. These horses appear to be able to race successfully with radiological evidence of OA of the femorotibial joints. Direct trauma to the stifle may result in soft tissue and bony injuries as in other types of horses. Trainers often are concerned that a horse may be locking its stifles, but this generally resolves with increased fitness, and sectioning of the medial patellar ligament is rarely necessary.

Chapter 110

The Racing Quarter Horse

Nancy L. Goodman

HISTORY AND DESCRIPTION OF THE SPORT

Racing Quarter Horses (QHs) are the sprinters of the racing world, competing at distances of 220 yards (one furlong, 201 meters) to 870 yards (795 meters). The explosive power exerted while leaving the starting gate and the ability to attain speeds of more than 50 mph (80 km/h) to run 440 yards (402 meters) in less than 21 seconds distinguishes the QH from other racing breeds. The American QH originates from colonial Virginia in the 1600s where imported English Thoroughbreds (TBs) were crossed with "native" breeds of Spanish descent to produce a compact, heavily muscled horse that excelled at running short distances. They were known as Quarter Pathers or Quarter Milers, named after the quarter-mile distance at which they excelled. The first race records came from Enrico County, Virginia, in 1674, where match races were run down village

streets and in small level fields. Gambling on races was popular at the time, with plantations changing hands over lost bets.¹

When settlers moved west with their horses, racing grew along with the popularity of the breed recognized for its versatility for ranch work and innate "cow sense." The first official QH racetrack was Rillito Park in Tucson, Arizona, opening in 1943. The American Quarter Horse Association (AQHA) was formed in 1940 to register and preserve the breed that presently represents the largest breed association in the world with more than 3 million members. QH racing is now nationwide and spans over five countries on three different continents. In North America alone, \$123 million in purse money was paid out in 2007.¹ Many racing QH owners, trainers, and jockeys raise horses or participate in Western performance events (roping, cutting, reining, showing, and rodeo events), and they take deep pride in the accomplishments of their horses. Winning the All American Futurity, held each year on Labor Day at Ruidoso Downs, Ruidoso, New Mexico and featuring a \$2 million purse (\$1 million going to the winner), has been the dream of most everyone in the industry. Los Alamitos Racetrack, a predominantly QH track in southern California, offers at least five races during the year with high dollar purses, with the Los Alamitos Two Million Futurity being the richest. The Champion of Champions race held at the end of the racing year is the most prestigious race

for older horses, representing winners of the top races during the year.

Emphasis in the sport is on 2-year-old racing (Futurities), requiring qualifying heats where horses with the 10 fastest times compete in a final 2 weeks later. Horses must be nominated to Futurities with periodic payments to maintain eligibility. The same applies to Derbies held for 3-year-olds, but the purse money is less than for 2-year-olds. Yearling sale prices are driven by precocious, nicely conformed, and well-bred individuals to compete in these lucrative Futurities at 2 years of age and then Derbies the following year.

The AQHA Racing Challenge is a program that was designed to provide more racing opportunities for older American QHs. At this time, 59 races take place in 11 regions across the United States, Canada, Mexico, and South America throughout the year. The horses compete in one of six different types of races, depending on age and ability. The series culminates with a championship night held in different locations.¹

The AQHA stud book has remained open to the breeding of TBs ever since the QH breed was formally established. Breeding to TBs is a useful outcross to expand an otherwise small gene pool and maintain the classic quarter-mile distance of 440 yards because some QHs run best at even shorter distances of 300 to 350 yards. Unlike the Jockey Club, artificial insemination is the norm for breeding, and embryo transfer is popular.

TRAINING THE RACING QUARTER HORSE

Horses are usually broken in the latter part of the yearling year to prepare for racing as 2-year-olds. They are not allowed to race before March of the 2-year-old year, and they are restricted from racing 440 yards until later in the year.² The early races are very short (220 to 300 yards), and the training schedule is light compared with the racing TB. Most of the 2-year-old QHs are very precocious, big bodied, and naturally fast. They can perform well with a low level of fitness, possibly a risk factor for injury. Once they are fit, they gallop fewer days than does a TB, and fitness in many older racehorses is maintained using a mechanical horse walker at the barn. To race for the first time, the horse must have two satisfactory morning works (qualifying). They generally work from the gate in "sets" of two horses at a time for a specific distance.

LAMENESS RELATED TO TRACK SURFACE

QHs race on varying track surfaces around the country, but trainers prefer a firmer surface when possible because a loose or sandy surface poses problems with breaking at speed from the starting gate and getting enough traction for sprinting at high speeds. A new set of injuries is seen when racing on a sandier type of track, especially superficial digital flexor (SDF) tendonitis. Hindlimb lameness, muscle strains, back soreness, and suspensory injuries are also increased. The firmer track is favored, but it may lead to the high incidence of joint and bone injury seen as a result of greater concussive forces. No statistics are available at this time for QH injuries racing on the newer synthetic tracks.

CONFORMATION RELATING TO LAMENESS

Conformational factors that may contribute to lameness in the forelimb are relative large body mass, poor carpal conformation (back at the knee and bench kneed), upright pasterns, and small feet. Major hindlimb conformational defects (sickle hocks, cow hocks, too straight in the stifles) are undesirable in the QH racehorse because breaking sharply from the starting gate is necessary to be competitive. Any serious hindlimb lameness may limit the horse's usefulness.

LAMENESS EXAMINATION

There is no set procedure for lameness examination, but a systematic approach is essential for completeness. An efficient approach is required, however, because many trainers like to examine every horse before it is entered to race. Soundness is imperative for optimum racing performance in the QH breed because races are so short and therefore won or lost by photo finishes on a regular basis. Horses with lameness may be fractious in the starting gate, and those with hindlimb lameness may be slow to break from the gate. Close lameness monitoring is required to maintain QHs in peak condition, and intraarticular therapy is frequently used because of the high level of joint trauma associated with the speed and concussion in these elite athletes.

Watching the horse walk out of the stall and down the shed row is useful and a good time to obtain a history from the trainer or barn foreman. A QH with a sore carpus may be noted immediately by a characteristic wide placement of the limb while walking. History is very useful, such as "the horse was getting hotter than usual at the track this morning," or "he is digging a hole in the stall and standing in it." Large barns often keep records of lameness work on each horse, and it is always useful to quickly review past radiographs and joint injections. Observing the horse walk and jog on a hard level surface may accentuate the lameness and aid in diagnosis. Hoof testers should always be used to define foot pain. Joint flexion and palpation are particularly useful owing to the high prevalence of joint problems.

When flexing the carpus, if the limb is raised forward and upward so that the radius is in the horizontal position, the veterinarian may observe an immediate tell-tale withdrawal response of the neck and shoulder muscles as a response to pain. Relaxing the limb, the joints are palpated by placing the thumbs along the individual dorsal borders of the carpal bones while the fingers apply pressure behind the joint to further localize the pain causing lameness. Moving in a distal direction, the dorsal aspect of the metacarpal region, suspensory ligament (SL), digital flexor tendons, and any splints should be palpated for a painful response. The fetlock is flexed, and the suspensory branches are palpated. The distal interphalangeal (DIP) joint is palpated for heat and excessive joint effusion. The digital pulse amplitudes should always be checked because they frequently will be elevated in horses with acute problems of the foot. Excessive synovial effusion, tenderness to palpation, and heat or filling in a specific area of the limb should be noted. The horse's back, loin, and gluteal muscles are briefly palpated and observed for asymmetry, and then

the separate compartments of the stifle are palpated. The medial femorotibial joint is the most common area of soreness in the stifle and may or may not have effusion. A positive Churchill test may be indicative of hock soreness and is quickly performed before palpating the distal aspect of the limb. The history of a poor performance (especially leaving the gate) or recognition of hindlimb lameness at the initial jog usually prompts a more complete examination, with proximal and distal limb flexion tests.

Diagnostic blocks are used when necessary to localize the lameness (see Chapter 10).

IMAGING CONSIDERATIONS

Because of the high incidence of joint injury, digital radiography is the most frequently used modality. The carpus and fetlock are the joints most commonly examined radiologically. Ultrasonographic examination is used for definition of suspensory, tendon, and joint injuries. Ultrasonographic examination is generally unrewarding for detection of proximal suspensory injuries in the QH. SDF tendonitis occurs with varying frequency, depending on the characteristics of the racing surface, and lesions vary widely in severity. Nuclear scintigraphy is used less than in the TB, but it is especially helpful in the diagnosis of tibial stress fractures.

SHOEING

The most serious shoeing problems in the QH are the same as in the TB: long toe, low excessively sloping heel, and medial-to-lateral hoof imbalance. Most racehorses are shod close to or on race day. Therefore corrective shoeing is not used as often as needed in many horses because of the risk of sore feet on race day. Horses race in aluminum shoes, and various kinds of pads are used for foot sore horses, including rim pads, wedge pads, full plastic pads, and even full aluminum pads with an assortment of different hoof packings. The most controversial topic at the moment is the use of toe grabs. Toe grabs have been associated with catastrophic injury in the racing TB, and use of these shoe additives is restricted in some states. Historically, many QH racehorses have raced with high toe grabs (>6 mm) to prevent stumbling and slipping from the starting gate and to maintain traction at high speeds. Now many QHs race without a toe grab or a 2-mm toe grab in front. Some leading trainers of QHs believe that the injury rate has been greater with the recent change to smaller toe grabs at the shorter sprinting distances.

A racetrack study including TBs, QHs, and other breeds showed that the prevalence of underrun heels was a significant risk factor for suspensory apparatus failure. The length of toe grabs was not shown to be significant in this study.³ Further investigation of toe grabs in relation to racing surfaces is necessary.

TEN MOST COMMON LAMENESS CONDITIONS OF THE RACING QUARTER HORSE

1. Synovitis of the carpal and metacarpophalangeal joints
2. Arthrosis of the distal interphalangeal joint and problems associated with the foot
3. Dorsal metacarpal disease
4. Osteochondral fragmentation of the carpus
5. Osteochondral fragmentation of the metacarpophalangeal joint
6. Distal hock joint pain
7. Stifle lameness
8. Proximal suspensory desmitis
9. Tibial stress fractures
10. Miscellaneous fractures of importance

SPECIFIC LAMENESS CONDITIONS

The following lameness conditions are the most relevant for the QH racing breed. Most of the topics are covered extensively in other chapters, and therefore this section is meant as a review of QH injuries and differences from those of the TB.

Synovitis of the Carpal and Metacarpophalangeal Joints

Synovitis of the carpus is the most frequent condition seen in the young racing QH. Back-at-the-knee conformation is common, and this predisposes to carpal injury during hyperextension of the joint while running. Many 2-year-olds have a large body mass and are inherently fast sprinters, reaching very fast speeds without much conditioning. Synovitis is characterized by heat and synovial effusion of the affected joints, with the absence of radiological changes. Lameness may be present but is generally not severe. Carpal flexion and palpation are used to localize the affected joints. Symptomatic treatment includes the use of ice, leg sweats or poultice, and nonsteroidal antiinflammatory drugs (NSAIDs). Intravenous hyaluronan (Legend, Bayer HealthCare, Animal Health Division, Shawnee Mission, Kansas, United States) or intramuscular polysulfated glycosaminoglycans (PSGAGs) (Adequan, Luitpold Pharmaceuticals Inc., Animal Health Division, Shirley, New York, United States) are often used as systemic treatment. Intra-articular therapy is very effective, with a good response from corticosteroids with or without hyaluronan.

The metacarpophalangeal joint of the forelimb is another frequent site of pain causing lameness in QHs. Heat and synovial effusion are the first signs of synovitis, along with a varying degree of lameness. The condition is often bilateral, and radiological examination is negative. In my opinion, capsulitis does not occur with the same frequency as in the TB because QHs in training do far less galloping than TBs; therefore much less stress is placed on the soft tissue structures of the metacarpophalangeal joint. The treatment is the same as for carpal synovitis. If the condition does not resolve with intraarticular therapy, or if it recurs rapidly, the training program should be altered, or the risk of further joint damage is likely, with osteoarthritis (OA) the end result. Many 2-year-olds are entered in numerous Futurities, so training revolves around these races. Trainers try to keep horses on schedule for these race dates, without sustaining injuries that jeopardize the racing careers or require extended layup periods.

Arthrosis of the Distal Interphalangeal Joint and Problems Associated with the Foot

DIP joint synovitis is a clinically significant cause of lameness in the QH.⁴ The breed is well known for having

undersized feet in relation to the body size, and this, coupled with the tendency for racehorses to develop a long toe and an excessively sloping heel, probably leads to greater stresses to the foot than in other breeds. QHs also have short upright pasterns, and they race at higher speeds on a harder track surface. Bilateral forelimb lameness is seen that can be accentuated by jogging on a hard surface. The stride is shortened with a transfer of weight to the hindlimbs. Horses typically respond to the application of hoof testers over the central third of the frog (as in navicular syndrome). Increased digital pulse amplitude is usually evident, and DIP effusion may be palpated above the coronet in many horses. Younger horses (2- and 3-year-olds) with synovitis show a greater degree of localizing inflammatory signs than older horses with chronic OA.⁵

Intraarticular analgesia may be used to localize the pain causing lameness, and I use intraarticular analgesia in combination with intraarticular medication when necessary to confirm the diagnosis. Radiographs are frequently normal but may show some degree of radiolucent changes along the margin of the distal phalanx and, rarely, radiological changes associated with navicular syndrome. OA of the DIP joint occasionally will be evidenced by the presence of osteophytes involving the distal aspect of the middle phalanx or the extensor process of the distal phalanx. A generalized suspensory soreness, as well as soreness in the area of the bicipital bursa, is often palpated secondary to inflammation of the DIP joint. Back pain may also be associated with the presence of sore feet and can be detrimental to racing performance because of the horse's reluctance to break sharply and extend its stride.⁴ These secondary clinical signs usually disappear after resolution of the foot soreness.

Antiinflammatory medications and corrective shoeing are used to treat DIP joint synovitis. The shoeing is in accordance to individual needs, most commonly backing up the shoe as much as possible and protecting the sole. A wide variety of pads are used, including rim pads, full pads, and aluminum pads with various sole packings. Wedge pads or shoes may be used to correct the low heel conformation, but care must be taken because often the heel pain is exacerbated. Some horses are trained in bar shoes until they are ready to race. NSAIDs (usually phenylbutazone) are used, and the feet are iced twice daily during the acute stage.

Intraarticular corticosteroids are effective in relieving pain. Betamethasone esters or triamcinolone acetonide, with or without hyaluronan, is preferred especially if frequent joint injection is necessary. In my experience, frequent use of methylprednisolone acetate (Depo-Medrol, Pharmacia and Upjohn Co., Kalamazoo, Michigan, United States) in the DIP joint will produce severe OA over time.

Other important common problems of the foot include bruises, abscesses, grabbed quarters, and quarter cracks, which are discussed in Chapter 28.

Dorsal Metacarpal Disease

Bucked shins and stress fractures of the dorsal aspect of the third metacarpal bone (McIII) are mainly problems of the 2-year-old QH racehorse but are occasionally seen in a 3-year-old. Dorsal metacarpal disease is basically a bone remodeling phenomenon of the dorsal aspect of the McIII

along the lines of stress, resulting in various degrees of periostitis and osteoporosis.⁶ The incidence is less now that trainers understand this bone remodeling process as it relates to exercise. There are four categories of this syndrome in QHs⁵:

1. The acute stage is seen when the horse's shin is hot and extremely sensitive to touch and the gait is "peggy" but radiographs are normal. This would be after a race or qualifying work.
2. "Shin splint" is used to describe a pea-sized bump seen directly below the carpus in association with considerable lameness. It is detected by manual palpation while sensitivity in the remainder of the shin is absent. Radiologically, a small area of periostitis is present.
3. The chronic shin stage is seen with horses that have not responded to treatment, and there is thickening over the dorsal aspect of the metacarpal region. Horses show little pain to palpation but are sore to jog and usually suffer from poor racing performance. Signs of periostitis and remodeling of the dorsal aspect of the McIII are seen radiologically.
4. Stress fractures are most often seen in 2-year-old QHs in contrast to TBs, which often sustain stress fractures from 3 to 5 years of age.⁶ Many of the fractures are longitudinal and cannot be seen to exit the cortex. The stress fractures may be present bilaterally, and the dorsolateral cortex of the McIII is the most common location, as in the TB. Longitudinal fractures heal well with rest, and surgery is not indicated.

The treatments are variable, depending on the owner, trainer, and the horse's racing schedule. Extracorporeal shock wave therapy is a popular treatment, but some of the older methods such as electrical hyperfercation, pin firing, and periosteal scraping are still used. They are all used with varying periods of rest depending on disease severity.

Osteochondral Fragmentation of the Carpus

The incidence of osteochondral fragmentation (chip fractures) of the carpus is very high in the racing QH. Numerous chip fractures are often seen, and many times they are bilateral. The distal aspect of the radial carpal bone is the most common site for a chip fracture, followed by the proximal aspect of the intermediate carpal bone. It is not uncommon to have distal radial carpal chip fractures in both middle carpal joints and proximal intermediate carpal bone chip fractures in both antebrachiocarpal joints in the same horse.⁷ Most are the result of cyclic trauma leading to alteration in bone structure.⁸

The diagnosis is generally made by physical examination and radiological assessment to confirm the location of the fragments. The lameness is fairly obvious; most horses have a characteristic wide placement or circumduction of the involved limb at the walk. Most horses are sensitive to flexion of the carpus and palpation of the dorsal aspect of the carpal bones. Heat and synovial effusion are often present. Arthroscopic surgery is the treatment of choice, although some less valuable claiming horses are injected with corticosteroids and raced. Distal radial carpal fractures in particular are associated with progressive cartilage damage and OA if the horse continues to race with a chip fracture. Preoperative radiographs of the contralateral carpus often reveal chip fractures. Many QHs

have numerous surgeries because of the high incidence of osteochondral chip fragmentation.

Occasionally tearing of the medial palmar intercarpal ligament is seen with or without a chip fracture. The condition is suspected when intraarticular analgesia eliminates lameness, but there are no obvious radiological abnormalities, or only a small fragment can be seen. The horse shows a disproportionate degree of lameness compared with the radiological findings. The diagnosis of tearing of the medial palmar intercarpal ligament can only be confirmed by arthroscopic surgery.⁹

Osteochondral Fragmentation of the Metacarpophalangeal Joint

Intraarticular chip fractures of the dorsal, proximal aspect of the proximal phalanx are commonly seen in the forelimb of racing QHs (but less commonly than carpal chip fractures). These fractures are considered to be traumatic hyperextension injuries. They occur primarily on the medial aspect but may also occur laterally.¹⁰ Horses usually exhibit lameness and synovial effusion and are positive to flexion of the fetlock joint. In some horses there are large fragments (especially compared with those fragments occurring in TBs), with a long frontal component. It may be necessary to use a flat blade knife to surgically remove the fragment from the joint capsule during arthroscopic surgery (Figure 110-1).

OA may be seen in association with chip fractures of the proximal aspect of the proximal phalanx especially in older horses, manifested as wear lines and erosions on the distal articular surface of the McIII.¹⁰ Defects on the palmar distal aspect of the McIII are far less common than in the TB, but they do occur in older QHs, and the prognosis is similarly poor.

Fragments of the palmar and plantar aspects of the proximal phalanx are seen less frequently than are dorsal fragments and are not always a source of lameness.¹¹ They are removed arthroscopically when clinically relevant.

Fig. 110-1 • Lateromedial digital radiographic image of a metacarpophalangeal joint in a racing Quarter Horse with a large osteochondral fracture (arrow) of the dorsal, proximal aspect of the proximal phalanx. Large dorsal plane fractures are common in the racing Quarter Horse. (Courtesy Dr. C.W. McIlwraith, Ft. Collins, CO, United States.)

Fractures of the proximal sesamoid bones (PSBs)—apical, abaxial, and basilar—are relatively common in the QH, despite such fractures being considered fatigue-related injuries.

Distal Hock Joint Pain

Lameness associated with the pain arising from the distal hock joints, as well as other hindlimb lameness, is associated with a failure to break sharply from the starting gate. Proximal limb flexion tests may be equivocal, but a positive Churchill test (see page 60) along with a history of poor performance may be indicative of distal hock joint pain, although a negative test does not rule this out. The condition is usually bilateral, and the horse may track closely behind or a hindlimb may cross axially during protraction when observed from behind. Horses that wear patches behind to protect from scalping or horses with laceration marks seen on the medial aspect of the hock are highly suspect for distal hock joint pain. Radiographs are negative in many instances, or subtle abnormalities may be seen. Intraarticular corticosteroids are effective at relieving pain and/or improving performance. Even though the tarsometatarsal and centrodistal joints are low motion joints, maintaining articular cartilage is important because these joints rarely fuse spontaneously. Betamethasone esters and triamcinolone acetonide have been shown to have fewer deleterious effects on cartilage than methylprednisolone acetate.^{12,13} If methylprednisolone acetate is used, low doses should be considered (20 to 40 mg).

Stifle Lameness

The most common site of stifle pain is the medial femorotibial joint, and this is the same as in the racing TB. Stifle pain can cause poor performance. The horse may be positive to proximal limb flexion or palpation, but usually intraarticular analgesia is required to localize the pain causing lameness. It is not always clear whether the condition is synovitis or early OA. Radiological examination is useful to assess the joint and rule out certain conditions. Ultrasonographic examination is useful to identify soft tissue lesions.¹⁴ Most horses with stifle pain respond well to intraarticular therapy, but if lameness persists diagnostic arthroscopy is necessary to make a definitive diagnosis. Lameness associated with the femoropatellar joint is often accompanied by joint effusion. In recent years most osteochondritis dissecans lesions are removed surgically before a horse starts racing. Upward fixation of the patella may be a problem in immature horses in early training.

Subchondral bone cysts of the medial femoral condyle can be an important problem. Arthroscopic surgery with injection of triamcinolone acetonide into numerous areas of the cyst lining has been recently reported as successful and is now the preferred treatment.¹⁵

Proximal Suspensory Desmitis

Forelimb proximal suspensory desmitis (PSD) is usually seen as an acute, profound lameness (grade 4 of 5) the day after a race and often affects the fastest horse in the trainer's barn. The horse may walk on the toe, without dropping the heel to contact the ground. Such severe lameness associated with PSD rapidly subsides, similar to that

seen in QHs with a stress fracture of the third carpal bone. If digital palpation is unrewarding, perineural analgesia of the lateral palmar nerve may be necessary to localize the pain causing lameness without blocking the middle carpal joint. Radiography and ultrasonography should be performed. Nuclear scintigraphy may be used but is not usually necessary for the diagnosis. QHs with acute PSD usually respond well to shock wave treatment and altering the training schedule as necessary.

Tibial Stress Fractures

Stress fractures of the tibia are seen in young horses about the time of their second qualifying work or first race. Diagnosis has become more common with access to nuclear scintigraphy. The lameness is unilateral and severe; the left hindlimb is affected most commonly. This may be because horses are pulling up quickly from a high rate of speed before entering a left-hand turn on the race-track. Unlike in the TB, in which tibial stress fractures occur most frequently in the caudolateral cortex, the most common location of tibial stress fractures in the QH is the distal medial aspect of the tibia.¹⁶ Nuclear scintigraphy is the most accurate means of diagnosis; digital radiography performed 7 to 10 days after injury may identify a lesion. Rest is required for at least 90 days before resuming training.

Miscellaneous Fractures of Importance

The three most common fractures resulting in catastrophic injury in the racing QH and TB are those of the PSB, the McIII, and the humerus.¹⁷ Although most often associated with racing and fatigue in TBs, biabaxial and comminuted PSB fractures occur in the QH with resulting disruption of the suspensory apparatus and the integrity of the MCP joint. Fractures of the McIII and the humerus are a cause of catastrophic injury in the QH. Horses generally are able to walk after shoulder injury, but the definitive diagnosis is usually made the next day when the pain and swelling are localized.

Another important injury is severe carpal bone fractures (slab fractures and comminuted fractures), many of which are amenable to surgery. Whenever pain causing severe lameness is localized to the carpus, a thorough radiographic examination, including skyline images, is necessary to ensure that degenerative lesions, incomplete sagittal fractures, and any nondisplaced fractures may be seen before a catastrophic injury occurs. All the recognized third carpal bone fractures can be seen in the QH, but a higher percentage of large dorsal plane slab fractures involve both the radial and intermediate facets than in the TB (Figure 110-2). The slab fracture is often displaced, with the distal margin of the radial carpal bone collapsing into the proximal aspect of the third carpal bone fracture site (Figure 110-3). Internal fixation using screws placed in lag fashion is necessary for proper healing and to prevent further collapse of the joint.

Fig. 110-2 • Dorsoproximal-dorsodistal (skyline) digital radiographic image of the distal row of carpal bones in a racing Quarter Horse with a large dorsal plane slab fracture (arrows) of the third carpal that spans the entire radial and intermediate fossae. (Courtesy Dr. C.W. McIlwraith, Ft. Collins, CO, United States.)

Fig. 110-3 • Lateromedial digital radiographic image of a racing Quarter Horse with a large, displaced dorsal plane slab fracture of the third carpal bone (C3). With dorsal displacement of C3 there is distal movement of the overlying radial carpal bone causing carpal instability. Prognosis for future racing is guarded, and surgical repair is necessary. (Courtesy Dr. C.W. McIlwraith, Ft. Collins, CO, United States.)

Comminuted carpal fractures caused by slab fractures involving both rows of carpal bones are catastrophic injuries seen in QHs. Challenging, salvage surgical procedures, such as partial arthrodesis or panarthrodesis using numerous bone plates, are necessary.

Although less frequent, fractures of the lumbosacral vertebrae are particularly devastating because they not only result in the death of the horse but as a result of the horse falling on the jockey, they often also result in severe injury to the rider.

Lameness in the Arabian Racehorse: Middle East and North America

Robert Andrew Dalglish and Mark C. Rick

HISTORY OF RACING

The Arabian racehorse originates directly from the Thoroughbred (TB) foundation sires of all light or hot-blooded horses. In the seventeenth century, these TB sires—the Darley Arabian, Godolphin Barb, and Byerly Turk—were imported to England and bred to the Queen's mares. The Arabian was used originally as a war horse, and although the true beginnings of the Arabian horse are under a shroud of mystery and legend, the consensus is that the Middle Eastern desert Bedouin tribes played a large role in the breeding and early development of the breed.

Throughout the Middle East and Europe, Arabian racing and performance are more deeply rooted than in North America. The popularity of Arabian racing has grown enormously in the United Kingdom in the last 15 to 20 years, with a growing number of professional trainers and jockeys and a progressive increase in prize money, in part because of the high Middle Eastern sponsorship. Arabian racing in North America and around the globe is less popular, and the number of races is fewer and the amount of prize money is less compared with TB, Standardbred, and Quarter Horse racing.

The Arabian Horse Registry of America, founded in 1908, includes many types and uses. Known for stamina, speed, and elegance, Arabian horses often were bred and raised for showing in halter and performance classes. In the latter part of the twentieth century, Arabian horse popularity and breeding selection shifted to criteria based more on aesthetics than athleticism.

The Arabian racehorse lineage reflects more athleticism than is found in Arabian show horses. Consistent winners often are more heavily muscled and have stronger hindquarters with a more sloping croup and a lower head and neck carriage than a typical Arabian show horse. Recent influx of new breeding lines has given rise to concern and controversy over the purity of the lineage and the possible infusion of impure Arabian blood. Certain new stallions appear to be much taller and longer, with a body type similar to the modern day TB racehorse. Constant vigilance and careful documentation of lineage is required to preserve the pure Arabian racehorse breed.

Arabian racehorses race on the same surfaces as TB racehorses. In North America selected meets are held from California to Delaware, from Florida to Michigan, in Colorado, Texas, and Washington, and at a few other tracks. Arabian racehorses perform in fair meets, allowance races, claiming races, and futurity nominated stakes races. Racing

Arabian horses also compete in the United Kingdom, Poland, France, Russia, and South America and in many Middle Eastern countries. In North America, racing begins on March 1 of the 3-year-old year. Race distances are similar to those for TB races, but the length and configuration of the racecourses vary. Shorter sprint distances, 4½ to 6 furlongs, often are run on the small tracks, whereas the longest race (2 miles [3.2 km]) is usually run on a large track. Typically, races are 4½ furlongs to 1¾ miles (881 m to 2.8 km). In the United Arab Emirates (UAE) races are 5 to 12 furlongs (1 km to 2.4 km), and horses race on both dirt and turf. A sound Arabian racehorse may compete as often as every 7 to 10 days, but most are given 2 weeks between races. Because relatively few Arabians are raced, lack of entries may mandate racing whenever enough horses are entered to meet race conditions rather than when trainers and owners prefer. Racing in the United Kingdom starts in late April. Until 2001, horses did not race until 4 years of age, but in 2001 a restricted number of races for horses 3 years of age were introduced. These are high-value races and also attract horses trained in France and other European countries. Races range from 5 furlongs to 3 miles (1 km to 4.8 km). In the UAE, Arabian races average 9.5 runners.

In 1999 the International Federation of Arabian Horse Racing Authorities (IFAHR) was formed for the purpose of cooperation among all national and international Arabian horse racing associations throughout the world. The IFAHR is registered in France. Founding member countries were France, Germany, Belgium, the UAE, Qatar, Switzerland, the United Kingdom, Austria, Holland, Russia, Saudi Arabia, the United States, Turkey, Egypt, Spain, Sweden, Morocco, and Poland. In the UAE, Arabian horseracing has taken place for over two decades. Abu Dhabi, where Arabian horse racing takes place almost every week during the racing season from November to March, is the largest of the seven emirates and has also become the leader in international sponsorship of Arabian racing since 1996, supporting major races in countries such as England, the United States, France, Russia, Holland, and Belgium. The Gulf State of Qatar is also an important sponsor of international Arabian racing. Several UAE breeders maintain operations throughout Europe and the United States and are a constant force at international auctions, where stock is acquired to race in their domestic market and eventually to support breeding programs. The majority of Arabians racing in the UAE are from North American and French bloodlines. Breeding of purebred Arabian racehorses is now very popular; over 60% of the Arabian racehorses competing in the UAE today are bred in the UAE.

TEN MOST COMMON RACING-RELATED LAMENESS CONDITIONS IN THE MIDDLE EAST ARABIAN RACEHORSE

1. Metacarpophalangeal joint lameness
2. Superficial digital flexor tendonitis
3. Suspensory desmitis including proximal suspensory desmitis and avulsion fractures of the third metacarpal bone
4. Distal hock joint pain and osteoarthritis

5. Lameness of the foot
6. Myopathies
7. Stifle and carpal lameness
8. Back pain
9. Dorsal third metacarpal bone disease
10. Fractures of various bones, including stress fractures

TEN MOST COMMON RACING-RELATED LAMENESS CONDITIONS IN THE NORTH AMERICAN ARABIAN RACEHORSE

1. Dorsal third metacarpal bone disease
 2. Superficial digital flexor tendonitis
 3. Suspensory desmitis
 4. Stifle lameness
 5. Tarsocrural osteochondrosis and distal hock joint pain
 6. Back pain
 7. Proximal sesamoid bone fractures
 8. Metacarpophalangeal joint lameness
 9. Carpal osteochondral fragmentation
 10. Lameness of the foot
-

METACARPOPHALANGEAL JOINT LAMENESS AND CARPAL OSTEOCHONDRAL FRAGMENTATION

In North America, osteochondral fragmentation or chip fractures of the carpal and metacarpophalangeal joints occur in Arabian racehorses but less frequently than in TBs and Quarter Horses. Smaller body size, a more gradual training regimen, and older age of horses racing likely account for the difference in incidence. However, in Middle East Arabian racehorses, lameness associated with the metacarpophalangeal joint is the most common problem encountered; carpal pain associated with osteochondral fragmentation is unusual. Early signs of arthrosis without chip fracture resolve quickly, with minor interruption in race training. The diagnosis of fetlock or carpal osteochondral fragments is straightforward. Arthroscopic surgery to remove osteochondral fragments is well accepted and successful. The prognosis depends on location, size, duration, previous treatment, and amount of associated cartilage damage. Horses with acute osteochondral fragments with only mild cartilage damage have a good prognosis. The decision for surgery often is based on economic factors.

Proliferative synovitis (villonodular synovitis) and associated fragmentation of the dorsal proximal aspect of the proximal phalanx occurs in the young Arabian racehorse. Horses have characteristic signs of effusion and a noticeable dorsal swelling. Dorsal swelling can be insidious and go unrecognized early in the disease process. Plain radiographs often reveal soft tissue swelling on the dorsal distal aspect of the third metacarpal bone (McIII) and osteochondral fragments of the proximal phalanx. Radiolucent changes in the McIII are seen in horses with severe proliferation. Ultrasonographic examination usually reveals enlargement of the dorsal synovial pad. One of us (MCR) recommends arthroscopic evaluation, removal of osteochondral fragments, and debridement of the synovial pad with a 5.2- or 3.4-mm suction punch (Dyonics, Andover, Massachusetts, United States).

In older Arabian racehorses, chronic osteoarthritis (OA) of the metacarpophalangeal joint is recognized. The trainer complains of poor performance or racing below previous levels. The metacarpophalangeal joint is enlarged from effusion or fibrosis and is warm. Horses usually respond positively to lower limb or fetlock flexion tests. Comprehensive radiographic examination should be performed. Radiological evidence of OA, such as marginal osteophytes of the proximal sesamoid bones (PSBs) and joint space narrowing, enthesophytes at capsular attachments, and soft tissue thickening, often is seen. OA of the metacarpophalangeal joint is seen frequently without osteochondral fragments and appears to be related to chronic wear and tear. In some horses OA can be managed by judicious use of intraarticular medication, but the prognosis for return to previous racing levels is guarded. In Middle East Arabian racehorses OA of the metacarpophalangeal joint and associated lameness are a major problem. Clinical signs include fetlock effusion, a positive response to lower limb and fetlock flexion tests, and a positive response to intraarticular analgesia and medication. Horses have typical radiological changes. The prognosis for continued racing is generally good, but numerous intraarticular injections of hyaluronan and corticosteroids are often needed to maintain adequate clinical comfort. Subchondral bone pain is suspected to be a factor in horses with few radiological changes or in those with increased radiopacity of the distal aspect of the McIII.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS

Superficial digital flexor (SDF) tendonitis (bowed tendon) is common and occurs from a combination of training overload and fatigue. Faulty forelimb conformation appears to be a factor, and the heavier Arabian racehorses from French bloodlines are more prone to injury of the superficial digital flexor tendon (SDFT) than those of North American origin. Lesions are found in the body and/or in the medial and lateral margins of the SDFT.

Occasionally horses run uphill at the end of a race, and SDF tendonitis occurs commonly under this condition. Sudden changes in track surfaces or training conditions are associated with an increased incidence of tendonitis. Injuries are often cumulative, and an initial injury that is overlooked or badly managed develops into a severe, career-threatening injury. Severe SDF tendonitis usually is recognized by the trainer because swelling, heat, and pain are present during palpation. More subtle swelling and pain are detected during careful palpation by a veterinarian. Thorough ultrasonographic examination is imperative to confirm the diagnosis. Careful assessment requires proper horse preparation, sedation, clipping and cleaning of the leg, and use of a high-quality ultrasound machine and a 7.5- to 10-MHz (or greater) linear transducer. Cross-sectional area (CSA) of the tendon and lesion, fiber alignment, and echogenicity of the lesion are evaluated, and any associated pathological conditions such as palmar annular ligament constriction, carpal tenosynovitis, or other soft tissue damage are assessed. Swelling is often mild if horses have been given local and systemic antiinflammatory therapy and rest. A slight increase in CSA measurement may be the only indication of SDF tendonitis, and comparison with the contralateral SDFT is mandatory. Initial management

includes rest, local ice and bandage application, and administration of systemic nonsteroidal antiinflammatory drugs (NSAIDs). Horses with mild or moderate SDF tendonitis often are sent to a layup or rehabilitation farm for 3 to 6 months, where a monitoring and controlled exercise program should be initiated. Follow-up examinations are performed at 2-month intervals to determine quality of the healing and the appropriate time to return the horse to race training. A slow return to training includes progressive walking, jogging, cantering, speed work (breeze), and then racing. Time span and progression depend on maintaining an acceptable ultrasonographic appearance during each incremental increase in stress or exercise level. Tendon splitting and desmotomy of the accessory ligament of the SDFT used separately or concomitantly are successful in horses with moderate or severe tendonitis. Intralesional injections of β -aminopropionitrile fumarate (Bapten; no longer commercially available) have been used successfully. More recently, intralesional injection of autologous stem cells derived from either bone marrow or fat and platelet-rich plasma (PRP) have been used with success. One of us (AD) has successfully used intralesional injection of the porcine urinary bladder matrix product A-Cell (A Cell Vet, Columbia, MD, United States) for Arabian racehorses with SDF tendonitis and suspensory desmitis.

Prognosis varies with the severity of the injury and the stage of racing when the injury occurred. Because many Arabian horses race as older horses, even stallions and mares, providing up to a year or more of rest is not uncommon, assuming the lesion heals, before returning the horse to race training. Horses with substantial SDF tendonitis often reinjure the same area of the tendon, develop a new injury of the previously damaged tendon, or develop tendonitis of the contralateral SDFT. SDF tendonitis does occur in the hindlimb, but less often than forelimb injury, and Arabian racehorses with hindlimb SDF tendonitis have a better prognosis than those with forelimb injuries.

SUSPENSORY DESMITIS

Forelimb suspensory desmitis is an intermittent problem of many Arabian racehorses early in training. Suspensory desmitis is not considered to be as debilitating or career limiting as it is for TB racehorses. A trainer often complains that the horse is sore, but overt lameness is not present. The differential diagnosis includes bucked shins, SDF tendonitis, and metacarpophalangeal joint and carpal joint lameness. Careful palpation reveals pain and enlargement of the suspensory ligament. Although ultrasonographic examination should be performed to confirm and grade desmitis, a pattern of subtle inflammation and soreness often precedes lesions detectable by ultrasonography. Scintigraphy may be useful but is seldom recommended. Suspensory desmitis is not severe, and most often the finding of body soreness in response to increased training intensity is the only apparent clinical sign. Traumatic disruption of the suspensory apparatus is rare. Horses with suspensory desmitis usually are kept at the track because they do not require or benefit from extensive time off. We recommend 1 to 2 weeks of rest or simply a decrease in training intensity to allow for tissue adaptation. The prognosis for horses with suspensory desmitis is good if the condition is

recognized early and horses are given a period of much-reduced work intensity and slow rehabilitation.

Proximal suspensory desmitis (PSD) is a clinically significant and often underdiagnosed cause of lameness in Arabian racehorses in the Middle East. One of us (AD) feels strongly that PSD and related injuries, such as avulsion fracture at the origin of the suspensory ligament on the McIII, are some of the most underrecognized sources of pain causing lameness in the Arabian racehorse. Pain associated with forelimb PSD and associated injuries can be abolished by performing lateral palmar analgesia at the level of the distal aspect of the accessory carpal bone after first performing low palmar (low four-point) analgesia. Infiltration of local anesthetic solution at the proximal aspect of the suspensory ligament can be used, but the combined carpometacarpal and middle carpal joints may be inadvertently desensitized; however, in Middle East Arabian racehorses these articular structures are rarely a source of pain. Once one forelimb is blocked, the horse often demonstrates contralateral forelimb lameness because PSD is often bilateral. Although changes associated with PSD can be identified ultrasonographically, often in Arabian racehorses ultrasonographic evidence of PSD is mild, but scintigraphically, focal areas of increased radiopharmaceutical uptake (IRU) of the proximal palmar aspect of the McIII are found, a finding that corroborates that bone injury is present. Although a diagnosis of PSD is often made in these horses, early stress fracture of the McIII may more appropriately describe this clinical syndrome, because in most horses PSD exists without concomitant McIII injury (Editors).

Treatment of Arabian racehorses with PSD and associated injuries includes an immediate removal from training, rest, and a controlled exercise program. Intralesional therapy with PRP and A-Cell and extracorporeal shock wave therapy have been used with some success. Generally, a good prognosis for return to athletic function is given. Avulsion fracture of the McIII at the suspensory ligament origin occurs less commonly and may cause sudden, severe lameness during exercise.

Proximal suspensory ligament injuries of the hindlimbs are less common than those involving the forelimbs and are more difficult to diagnose, but they are an important cause of pain causing lameness; they should be considered when investigating hindlimb lameness and carefully differentiated from distal hock joint pain.

TARSOCRURAL OSTEOCHONDROSIS AND DISTAL HOCK JOINT PAIN

Tarsocrural osteochondrosis is an occasional cause of hindlimb lameness. If bog spavin is recognized when the horse is a weanling or yearling, arthroscopic surgical removal of osteochondritis dissecans (OCD) fragments usually is performed then. However, horses may arrive at the racetrack or training stable with mild tarsocrural effusion. Moderate tarsocrural effusion is commonly observed in many Middle East Arabian racehorses without evidence of osteochondrosis. Although horses are usually not lame, trainers request that the joints be drained and injected with hyaluronan and corticosteroids. If lameness is observed, if a horse has a positive response to upper limb flexion, or if moderate effusion is persistent, then radiographs should be obtained. If OCD fragments are found, we recommend

arthroscopic surgery and a short (2- to 3-month) period of rest before training resumes.

Distal hock joint pain occurs in the Arabian racehorse and is seen most commonly after changes in track surfaces. These horses often do not push off or propel themselves well behind, may refuse to grab the bit or bow the neck, and use the front end to pull ahead, a gait that may lead to secondary forelimb lameness. Clinical signs often are lacking, and an upper limb flexion test may be only mildly positive. Radiological findings are often negative, but scintigraphic examination reveals IRU in the distal hock bones. OA of the centrodistal and tarsometatarsal joints is common in Middle East Arabian racehorses, and distal hock joint pain is the most common cause of hindlimb lameness. Intraarticular injection of corticosteroids produces a good response, and repeated injection is not deleterious to the future function of the hock (AD). Recently, adjunctive use of tiludronate has proved beneficial. Distal hock joint pain should be differentiated from pain originating from PSD.

LAMENESS OF THE FOOT

Although Arabian horses are alleged to have solid foot structure, they do get sore feet. Long-toe, low-heel conformation is not common. Arabian horses are protected from some of the lameness conditions of the feet simply because of small body size and weight. Sore feet develop after a fast workout or race on a hard, packed racetrack. Trainers often recognize signs, and the condition is managed using ice baths, NSAIDs, and 3 to 4 days of rest.

In the Middle East, lameness attributable to the distal interphalangeal (DIP) joint is characterized by effusion, a positive response to intraarticular analgesia, and a positive response to medication with hyaluronan and corticosteroids. The DIP joint is a relatively common source of pain causing lameness in the Middle East Arabian racehorse. Although marked radiological changes may not be apparent, a response to intraarticular therapy can be dramatic, but injections may have to be repeated to maintain comfort. Less commonly, in older Arabian racehorses, "navicular syndrome" is diagnosed as the cause of foot lameness. Horses may improve for a short time with intraarticular injections into the DIP joint. In horses with pain originating from the navicular bone without concomitant deep digital flexor tendonitis tiludronate is given adjunctively. Other common causes of foot-related lameness are abscesses, bruised heels and quarters, and poor foot balance.

MYOPATHY

In the Middle East one of us (AD) has managed many Arabian racehorses, especially those from certain bloodlines, with recurrent exertional rhabdomyolysis (RER). This condition can manifest as acute "tying-up" (usually following a change in management such as a return to training after a period of rest) or as a cause of poor performance in horses with subclinical, chronic elevations in the serum muscle enzyme concentrations of creatine kinase (CK) and aspartate transaminase (AST). RER appears to be caused by an inherited, intermittent, stress-induced defect in regulation of muscle contraction (see Chapter 83). RER can be successfully managed with exercise and dietary changes. Starch in the diet is replaced by rice bran (which can be

fed in specialized feeds). Ensuring that the horse has regular exercise including short periods of fast exercise is an essential component of the management of horses with RER. Acute RER invariably occurs during periods of submaximal exercise. The condition is monitored by regularly following blood CK and AST levels. CK is quickly excreted through the kidney, and therefore a chronic elevation in serum levels of CK is indicative of ongoing muscle damage. Because AST is metabolized in the liver, serum levels are slower to rise and fall during acute, initial muscle damage.

STIFLE AND CARPAL LAMENESS

In North America the most common source of hindlimb soreness is the stifle region. In the Middle East Arabian racehorse, stifle region pain is uncommon, as is lameness associated with the carpus, and these conditions are grouped together. Early in training a horse may become sore and stiff, usually bilaterally. Intermittent upward fixation of the patella is common as in other young sports horses. Stifle soreness is common in young horses shod with flat shoes and training on a soft track. Soft tissues around the stifle become inflamed. Clinical signs include a shortened stride and an unwillingness to extend the stride behind, or actual upward fixation of the patella, with characteristic stifle and hock extension and toe drag. With early detection, horses with stifle region lameness are assumed to have a soft tissue problem and are managed by decreasing training intensity and the administration of NSAIDs. Occasionally an internal blister is injected around the patellar ligaments, especially if evidence of upward fixation of the patella exists. If effusion of the femoropatellar joint accompanies the upward fixation of the patella, radiographs should be obtained. Results are usually negative, but some horses have underlying OCD of the lateral trochlear ridge of the femur. Surgical debridement is recommended, especially if a flaplike lesion exists. OCD lesions usually are detected early in race training if they are clinically important. In Middle East Arabian racehorses the most common source of stifle region pain is lameness related to osteochondrosis lesions, OCD, and subchondral bone cysts. In North America, subchondral bone cysts of the medial femoral condyle are rarely seen. Horses with subchondral bone cysts are treated by rest, injection with corticosteroids, or surgery. If radiographs reveal evidence of OA, such as enlargement of the medial tibial plateau, or if ultrasonographic examination reveals flattening, wrinkling, or other change of the medial meniscus, then the prognosis for racing is diminished. If subchondral bone cysts are discovered early in training, horses are best managed with arthroscopic surgery. The prognosis for a horse with a sore stifle, ligament laxity, and intermittent upward fixation of the patella is good, assuming a favorable response to alterations in training regimen. Lameness in Arabian racehorses with sore stifles appears similar to that seen in young TBs with tibial stress fractures, but the origin of pain is different. The prognosis for horses with osteochondrosis varies but is poorer if evidence of OA exists.

BACK PAIN

Primary hindlimb lameness causes secondary back pain in most Arabian horses, particularly those with primary

lameness of the stifle and hock joints. Often back pain resolves after management of the primary hindlimb lameness. However, treatment of back pain concomitantly allows earlier resolution of both problems. Exercise riders or jockeys may suspect back pain and often report a sensitivity or soreness over the top line. Horses usually show pain on palpation or when pressure is applied along the back. The back is palpated carefully, and pressure should be applied uniformly and gently. Thermography has been of some value in horses with back pain resulting from a poorly fitting saddle. The saddle can be evaluated thermographically and compared with any warm spots on the horse's back. Nuclear scintigraphy may reveal IRU in the summits of the dorsal spinous processes. Radiological examination may confirm overriding of the dorsal spinous processes. However, radiological and scintigraphic findings are often negative, and back pain is assumed to originate from soft tissues. Nonetheless, if back pain is severe, we suspect a bony source of pain. The back can be evaluated by ultrasonography, dorsally or rectally, for myositis, nerve root impingement or enlargement, and osteophytes associated with the vertebral articulations. Lumbosacral and sacroiliac pain is often detected in Middle East Arabian racehorses, and a positive response to pressure over the tubera sacrale may indicate that sacroiliac region pain is contributing to an abnormal gait, if present. IRU in the sacroiliac region can help establish a diagnosis, and one of us (AD) often injects corticosteroids in horses with this finding, not only to manage pain in these horses, but also to help establish a diagnosis.

DORSAL THIRD METACARPAL BONE DISEASE

Many racehorses trained intensely at speed at a young age experience the sore-shin or bucked-shin complex. Although intense training may not begin until the 3-year-old year and the Arabian racehorse is smaller in stature and weight than its TB counterpart, bucked shins remain a major cause of lameness requiring reduction in training intensity. Trainers are well aware of this problem and often can diagnose it accurately based on clinical findings and the observation of a sore horse, traveling short. A veterinarian usually confirms the diagnosis clinically, but in some horses radiography and occasionally scintigraphy are necessary. With advanced dorsal McIII cortical pain, typical dorsal cortical periostitis or a dorsal cortical fracture is seen radiologically (see Chapter 102). With periostitis comes intense, diffuse IRU, whereas focal IRU is seen in horses with a dorsal cortical fracture (see Chapter 19). However, scintigraphy is used more commonly to diagnose stress-related bone injury and stress fracture of other long bones in Arabian racehorses. Conservative management is preferred with rest, reduction in strenuous training, or return to the layup farm. Pin firing and blistering are not used routinely. Dorsal cortical fractures are rare, but if present, one of us (MCR) prefers surgical management using osteostixis (dorsal cortical drilling) or insertion of a bone screw placed in lag fashion in the dorsal cortex of the McIII. The prognosis is good.

Although this condition is recognized in Middle East Arabian racing, it does not appear to be as common as in North America, and horses are usually successfully managed conservatively.

FRACTURES OF VARIOUS BONES, INCLUDING STRESS FRACTURES

PSB fractures do occur in Arabian racehorses but are less common than in TBs. Clinical signs, management, and prognosis are similar to those in the TB racehorse (see Chapter 36). Other fractures, such as midsagittal fractures of the proximal phalanx and condylar fractures of the distal aspect of the McIII, are rare in North America. However, in the Middle East both medial and lateral condylar fractures of the McIII occur quite commonly. Lateral condylar fractures predominate. Horses with fractures of the proximal phalanx and condyles of the McIII are managed surgically. Less commonly, humeral and tibial fractures occur. Complete fractures are easily diagnosed and necessitate immediate euthanasia. Horses with humeral and tibial stress fractures often require scintigraphic examination for diagnosis but have a good prognosis if fractures are recognized early when incomplete and the horses are properly given complete box rest. Pelvic stress fractures are being recognized more frequently in Middle East Arabian racehorses; one of us (AD) believes that these fractures have been underdiagnosed. Scintigraphy usually produces a conclusive diagnosis. Avulsion fractures of the origin of the suspensory ligament from the McIII with or without associated PSD occur in the forelimbs and hindlimbs, cause acute-onset lameness, and are commonly diagnosed in the Middle East Arabian racehorse. Conservative management is successful, but prognosis is adversely affected by concomitant PSD.

PROCEEDING WITHOUT A DIAGNOSIS

Lameness in Arabian racehorse should be investigated in a logical manner as with all lameness examinations, taking into account the usual wishes of the owner and trainer to retain the horse in training if possible. In some horses in which joint pain is suspected but clinical signs are vague, a concurrent intraarticular injection of hyaluronan, corticosteroids, and local anesthetic solution can be used as a diagnostic and therapeutic approach. Occasionally, lameness is suspected but a diagnosis cannot be made. Horses with such lameness are characterized by a drop in performance, an increase in race times, a subtle gait change, a refusal to switch leads, a drop in class, or soreness, but no clinical signs of overt lameness are observable. In this situation, we usually recommend a whole-body scintigraphic examination, but correlating findings with clinical signs is often difficult. Comprehensive evaluation for poor performance considers not only a musculoskeletal problem but also cardiovascular and muscle abnormalities. Sometimes, Arabian horses may be thought to be more fragile and highly strung than other racehorses, and some trainers attribute poor performance to this portion of the horse's personality. However, Arabians are used for endurance riding (see Chapter 118), in which average speeds of more than 25 km/hr are often sustained over a course of 120 km, a fact that confirms the breed's strong metabolic endurance characteristics. One of us believes strongly that if an Arabian cannot endure race training, there is invariably a musculoskeletal defect or injury (AD).

Chapter 112

National Hunt Racehorse, Point to Point Horse, and Timber Racing Horse

Sue J. Dyson, Robert Joseph Van Pelt,
Kevin P. Keane, James Wood, and Anthony Stirk

DESCRIPTION OF THE SPORT

For as long as horses have been domesticated and ridden, they have been raced. The oldest record of racing in Britain shows that the Romans used to race their horses in Chester. Subsequently, little is known about any organized horse racing during the Middle Ages, but by about 1150 racing had become established at Smithfield, a horse market, where horses were tried and sometimes raced before sale. By the early part of the sixteenth century, racing had returned to Chester, where the prize for the winner in 1511 was a silver bell.

All of these races were on turf with no obstacles to negotiate. At about the same time that horses were competing for the Chester bell, fox hunting (rather than hunting deer or wild boar) started to become established and rapidly increased in popularity. One reason for this may have been the changing agricultural landscape as more and more land was enclosed, providing natural obstacles for those following the hunt to jump. Inevitably, rivalry developed among those who regularly followed fox hunts across country regarding who had the fastest horse, and a new sport was born, known as steeplechasing. The origin of the name is simple. Because no courses were defined over which the races could take place, the participants had to race from one church to another, using the high church steeple toward which they were heading as a landmark. The riders could choose their own route and had to jump a variety of fences such as hedges, banks, walls, timber fences, and brooks during the course of the race. The first steeplechase of this type was held in Buttevant in Ireland in 1752, when two neighbors raced between Buttevant church and the St Leger church, a distance of $4\frac{1}{2}$ miles (7.2 km).

Eventually this new sport was formalized, with specially constructed courses that allowed more participants to take part and more spectators to watch. The first such organized race meeting in Britain was held at St Albans in 1830. The Grand National was first staged in 1839, the National Hunt Steeplechase followed at Market Harborough in 1859, and the first meeting at Cheltenham (Prestbury Park), arguably the best known modern jump racing venue, was in 1898.

As the sport developed, regulating it became important, but the Jockey Club, which had been regulating flat racing since the mid-eighteenth century, regarded the new sport with suspicion. Accordingly, a separate National Hunt Committee was established in 1866 and continued to run

jump racing until 1969, when it and the Jockey Club merged to bring all racing, on the flat and over jumps, in Britain under one governing body. The National Steeplechase Association oversees racing over fences in the United States.

Modern National Hunt racing now consists of several categories, all run on turf on clockwise and counterclockwise courses. Horses run under similar rules in the United Kingdom, Ireland, and France. Elsewhere in Europe, racing over fences takes place but on a much lower scale. Most races are hurdle races or steeplechases, but some races run over more natural obstacles remain—some that are run over exclusively timber fences, and some, called *National Hunt flat races*, that are run without obstacles.

Apart from the fences, three major differences exist between National Hunt and flat racing, which are important in the epidemiology of the injuries that may occur in the different sports. These differences are the race distance, the age of the horses, and the weights of the riders. All National Hunt races are more than a minimum of 2 miles (3.2 km) compared with the minimum distance of 5 furlongs (1 km) on the flat, and the horses are at least 3 years of age. Forty percent of National Hunt Flat races involve horses of 4 years of age, a slightly higher percentage are 5 years of age, and less than 20% are 6 years of age or older. Most horses competing in flat races are 2 or 3 years old, but it is not unusual for horses over the age of 10 to race in National Hunt races, especially in steeplechases. Finally, National Hunt horses carry 10 stone (63.5 kg) to 11 stone 12 lb (75.3 kg), considerably more weight than flat horses.

Hurdle races are held over fences smaller than those encountered in steeplechasing. In Britain, most hurdles are derived from the simple portable fences used to create temporary pens for sheep, although small brush hurdles are being trialed. They are usually 72 inches (1.83 m) wide and must be not less than 42 inches (107 cm) from top to bottom bar and constructed of ash or occasionally oak. Several hurdle sections are placed end to end to produce an obstacle that must be at least 30 feet (9 m) wide. Each hurdle section consists of two uprights with pointed legs that are driven into the ground and five horizontal rails, between which is interwoven birch or another suitable material. Gorse, which is durable but has sharp thorns, is not permitted. The hurdles must be driven into the ground at an angle of 62 degrees so that the top bar is set back 20 inches (51 cm) from the vertical, and the effective height of the hurdle is 37 inches (94 cm). All of the exposed timber parts must be padded with a minimum of $\frac{1}{2}$ inch (1.3 cm) of high-density polyethylene or closed cell foam rubber (Figure 112-1).

Timber hurdles have the advantage that if a horse misjudges the fence and does not jump it cleanly, the hurdle gives way on impact. Old style hurdles were not padded as well as the modern versions and occasionally led to lacerations on the dorsal aspects of the hindlimbs, which could be extensive with degloving injuries of much of the metatarsal region. These injuries have been virtually abolished by the new padding.

In countries other than Britain and Ireland, timber hurdles are replaced by fences that look like small versions of steeplechase fences. Such fences also are seen on a small

Fig. 112-1 • A hurdle race. The jump of the leading horse, which has almost run through the hurdle, is awkward, the hindlimbs are positioned asymmetrically, and the horse's back is hollow.

number of racecourses in Britain, and proponents of these types of fences argue that they provide a better introduction to racing over obstacles for horses that ultimately are intended to be steeplechasers. This may be true, but only 35% of horses that run over hurdles convert to steeplechasing, indicating that hurdle racing has become a specialty sport that draws many of its participants from horses that have raced previously on the flat.

Steeplechases are run from 2 to 4½ miles (3 to 7 km) over fences that, with the exception of those at Aintree, over which the Grand National is held, have a standard construction. The course must have at least six fences per mile, one of which must be an open ditch, with the other plain fences. The plain fences must be a minimum of 54 inches high (1.37 m) and constructed of birch, or birch and spruce, in a frame. The use of gorse is not permitted. The base of the fence must be 72 inches (1.83 m) from front to back, with the thickness of the fence at its top not less than 18 inches (46 cm) (Figure 112-2, A). Plain fences usually have a guard rail on the face of the fence that usually is padded with the same material as the hurdles. An open ditch has similar overall dimensions, but the ditch in front of the fence, which may or may not be dug out, must be at least 72 inches (183 cm) from front to back and be delineated by a takeoff board that is up to 24 inches high (146 cm). Designers of racecourses also, if they wish, may include a water jump in steeplechases. These consist of a smaller fence, up to 36 inches (91 cm) high, with a 108-inch (2.74-m)-wide water ditch, which must be 3 inches (7.6 cm) deep, on the landing side of the fence.

Point to point races (see Figure 112-2, B), named because originally they were run from one point to another, represent the amateur branch of steeplechasing and are restricted to horses that have qualified to race by hunting with a

registered pack of hounds. Races for such horses also take place on licensed racecourses and are known as *Hunters' Steeplechases* (or Hunter chases).

Some races, notably in France, at Punchestown in Ireland, and at Cheltenham in Britain, are run over more natural obstacles, including banks and growing hedges. Timber races are held over upright (United States) or sloping (Britain) post and rail fences (Figure 112-3). To make the obstacles less dangerous, the top rails may be sawn through so that they will knock down if they are hit hard.

Finally, National Hunt flat races are staged for horses that have not run previously on the flat and are at least 3 years old. The races are intended to teach horses to acclimatize to the environment of a racecourse and the rigors of a race, without the additional hazard of obstacles. They also provide a way of demonstrating a horse's ability so that it can be sold. Colloquially, National Hunt flat races are known as "bumpers," because originally they were restricted to amateur riders, and the combination of inexperienced riders and horses led to their pejorative nickname.

NATIONAL HUNT HORSES

British and Irish National Hunt horses may be Thoroughbreds, which are registered in the General Stud Book, or non-Thoroughbreds, which are in the Non-Thoroughbred register. Many top-quality French jumping horses are of the Selle Français breed. Horses are started in jump racing by one of two routes. They are raced on the flat at 2 or 3 years of age before moving on to hurdling and possibly to steeplechasing, or they are bred specifically for National Hunt racing. Red Rum, who won the Grand National on three occasions, is an example of a horse that started racing

Fig. 112-2 • A, A steeplechase race in France. **B,** A point to point race. The fences are smaller than in steeplechase races, and the amateur jockeys tend to be less well positioned.

in flat races as a 2-year-old. In general, however, horses that graduate from the flat tend to stay in hurdle races, and only 35% of horses that race over hurdles go on to race in steeplechases. Geldings tend to predominate in both types of race.

Steeplechasers tend to be bred for that particular type of racing and are usually bigger-framed Thoroughbreds compared with flat racehorses. Breeding steeplechasers is less straightforward than breeding for flat races, because most steeplechasers are geldings, meaning that it is unlikely that males can be chosen based on racecourse performance. Finding performance-tested mares also is difficult, because the average age of steeplechasers is the highest of all racing categories, and by the time a mare has proved her ability, she may be past her breeding prime. Therefore most

stallions that are popular as sires of steeplechasers are horses that have shown stamina on the flat and then prove to sire successful progeny. Many mares that are used to breed steeplechasers are chosen because of pedigree rather than performance.

Once foaled, many horses destined for steeplechasing are left unbroken until 3 or 4 years of age, when they are often sold as National Hunt *stores* (horses bred specifically for National Hunt racing) intended to start a racing career at 4 or 5 years of age. This traditional system has been used for many years and could be said to have stood the test of time. Recently, National Hunt breeze-up sales have been introduced and are gaining in popularity. However, some research suggests that horses benefit from an early introduction to regular exercise and from early racecourse

Fig. 112-3 • A timber race. The horse is jumping well, and the rider is in good balance.

experience, and this may reduce the risks of injury.¹ Moreover, the later that horses enter training, the higher the risk of fatal injury.

TRAINING NATIONAL HUNT HORSES

At its simplest, training involves conditioning the cardiovascular, respiratory, and musculoskeletal systems of horses to tolerate maximal exercise. The skill of the trainer is to exert the horse sufficiently to achieve this while avoiding physical injury and without inducing an aversion to hard work. Human athletes, being motivated to succeed, tolerate extreme discomfort during training to achieve their goals. Horses have to be encouraged to exercise and never to anticipate that the result of exercise will be discomfort or pain.

Horses that move to National Hunt racing from flat racing receive the basic conditioning as yearlings and young 2-year-olds. Store horses, however, may do little regular exercise until they are virtually skeletally mature at 4 years. Because they are older, thinking that they require less time to adapt to exercise is tempting, whereas the reverse may be true. It is therefore essential that early preparation is graduated gently and that early signs of failure to adapt, such as sore shins or joint effusions, are noted and training intensity adjusted. If clinical signs go unrecognized or ignored, more serious skeletal defects may develop, such as stress fractures of the tibia, humerus, or pelvis, which may precede catastrophic fractures on the gallops or racecourse. Traditionally, store horses spent at least 6 weeks walking and trotting on quiet roads and tracks before they commenced any faster work. This initial slow preparation has now been abandoned by many trainers, partly because of the difficulty of finding a suitable safe, quiet environment and partly because of the economic pressure to see the horse on the racecourse.

Most trainers of National Hunt horses now use a simple adaptation of interval training over distances of about 1000 m, almost invariably up an incline that may be steep. An average morning workout would be an initial slow warm-up, followed by two brisk canters up the incline on an easy morning, alternating with three faster ascents on a work morning.

One of the most important aspects of training National Hunt horses is teaching them to jump appropriately. Hurdle races are conducted at a fast pace, and some trainers believe that horses that jump the obstacles without touching them, and with the same action as a show jumper, use energy unnecessarily and concede ground to rivals who jump low and flat. This is possible because the timber hurdles give way if the horse hits them, although the ease with which they do this depends on the ground into which the legs of the hurdles have been driven. Once horses have acquired this style of jumping, some trainers argue that the horse finds it difficult to jump the larger, more solid, steeplechase fences. This accounts for the relatively low number of horses that make the transition from hurdling to steeplechasing and the demand in Britain by some trainers for a brush hurdle that, although relatively small, has to be jumped with care. Specialist steeplechasers are encouraged to jump much as horses intended for other disciplines that involve jumping, and they jump low poles and logs, with and without a rider, before progressing to larger obstacles. However, the amount of training carried out over fences by steeplechasers is proportionately much less in the United Kingdom and Ireland than for event horses or show jumpers.

RACING NATIONAL HUNT HORSES

Jump racing developed as a winter sport, probably originally because of the connection with fox hunting, which

Fig. 112-4 • A faller at a point to point race. Note the extreme position of the hindlimbs.

also is conducted during the winter months. However, jump racing is now held in Britain throughout the year, although those courses that hold summer jump meetings are required to ensure by artificial irrigation that the ground conditions are kept no worse than good to firm. This is because epidemiological studies have shown that firm ground conditions are more likely to be associated with serious injuries. The reason for such a relationship is complex. It is probably related to the speed at which the horses travel, but other complex factors influence the interaction of the horse's foot with the ground under various conditions, some of which are related to ground hardness, and these require further research and elucidation. Jump racing remains seasonal, however, because the major races take place from November to March, and many horses spend a few weeks turned out during the summer. Seasonal racing influences injury management, because if a horse sustains a clinically significant injury in, for example, late February, the owner or trainer applies pressure for the horse to be ready for the next season—that is, to resume training by October of the same year.

Horses are trained by individual trainers spread throughout the United Kingdom, Ireland, and France and may travel long distances to compete. Therefore any single veterinary surgeon usually does not deal with more than four or five trainers and their horses. At race meetings the horses are subjected to prerace veterinary inspections, and each race is monitored carefully by veterinary surgeons driving on the outside of the track alongside the race and a veterinarian observing the entire race from an appropriate vantage point.

Point to point races are held from January to June. Point to point racing is an amateur sport, raced over obstacles that are smaller and softer versions of the steeplechase fences on licensed racecourses. Some horses that perform well in point to points successfully graduate to steeplechasing, and this route to steeplechasing is chosen by some owners in preference to hurdle racing, possibly after one

or more National Hunt flat races. While National Hunt horses run on average between four and five times per year, point to point horses may run more frequently during the season, because the race meetings are usually held at weekends. However, the average number of starts per point to point horse in 2000 was only three.

Because of the two distinct sources of horses that enter National Hunt racing, a wide variety of injuries is seen, ranging from injuries related to beginning training to degenerative injuries associated with overuse. In addition to the injuries sustained while the horse is in training, a National Hunt horse is more prone to injury after a fall than is a flat racehorse (Figure 112-4). It is also important to be aware that horses that are skeletally mature when they begin training (4- to 5-year-old store horses) still undergo the same pathophysiological processes that lead to stress fractures, albeit in different sites from the 2- or 3-year-old Thoroughbred. Because National Hunt racing continues throughout the year, the going under foot (footing) can vary, and extremes of both soft and firm going place the National Hunt horse under extra stress from injury.

A substantially higher death rate occurs in National Hunt racing compared with flat racing.¹⁻⁷ In a retrospective analysis of data from all starts from January 1990 to December 1999, 2015 deaths were recorded on racecourses from 719,099 starts.¹ The death rate per 1000 starts was substantially higher in steeplechasers (6.7; 34.5% of the total) and hurdlers (4.0; 43.4% of the total) compared with flat racehorses (0.9; 18.8% of the total). Spinal injuries occur much more frequently in hurdlers (19% of all hurdler deaths) and steeplechasers (23% of steeplechaser deaths) compared with flat racehorses (1% of flat racehorse deaths). Tendon breakdown injuries resulting in humane destruction at the racecourse were also substantially higher in hurdlers (20% of hurdler deaths) and steeplechasers (14% of all steeplechaser deaths) compared with flat racehorses (8% of flat racehorse deaths). Risk of mortality was associated with a

number of variables. With steeplechase horses a higher risk occurred in horses that started steeplechase racing at 8 years of age or older. The weight carried was also influential, with horses carrying more than 70 kg minimum weight being at greater risk. Races longer than 4 miles were associated with a higher risk than shorter races. Heavy going, resulting generally in slower speeds, reduced the risk. Good to firm or hard going increased the risk of mortality in hurdlers and steeplechasers.

TIMBER RACING

Timber racing is considerably more popular in the United States than in the United Kingdom and is more structured. Novice or stakes horses compete only against one another, with greater prize money for stakes races, the most valuable being the Maryland Hunt Cup. The most prestigious race in the United Kingdom is the Marlborough Hunt Cup. Historically the stakes races with the largest amounts of prize money have been open only to amateur jockeys; however, recent rule changes have allowed for professionals to ride in these races in the United States. Timber racing horses often have raced previously on the flat or over hurdles, are usually 6 to 12 years of age, and may have injuries from earlier racing, particularly osteoarthritis (OA) of numerous joints and stable superficial digital flexor tendon (SDFT) injuries.

TRACK SURFACE OR TRAINING SURFACE AND LAMENESS

The surfaces and terrain over which horses train vary extremely because the trainers are dispersed widely geographically. Much of the work is done on grass, but fast work often is done on all-weather purpose-built gallops.

Many horses hack up to a mile to and from the gallops, ensuring good warm-up and cool-down. However, the standard of maintenance of the gallops varies. Poor gallops with an inconsistent surface varying from soft to deep may increase the risk of tendon injuries or predispose horses to stumbling and accidents such as third carpal bone fractures. Many trainers are based in areas of chalk downland (natural rolling hills with a chalk subsoil), which drains well, but the large number of flints (sharp stones) in the soil may result in a high incidence of bruised soles or sole punctures unless the horses have well-conformed feet. The steepness of the terrain over which the horses do fast work may influence injury. An increased number of pelvic fractures was noted after a new gallop was laid, the last section of which was up a steep incline (RvP). In a yard of 40 horses, one or two horses per year sustained pelvic or tibial stress fractures, but after the new gallop there were seven ilial wing fractures (three right, four left), two sacroiliac subluxations (one bilateral, one right), and two tibial stress fractures. These injuries may have been caused by hind foot slippage. After the gallop was recontoured, the problem resolved.

The influence of falls on the nature of injuries is substantial.²⁻⁷ Most falls occur on landing over a fence. Falls may result from the horse or jockey making a jumping error, from interference by another horse still in the race, or from a loose horse that had previously unseated its rider. The fall of one horse may result in the fall of one or more other horses (Figure 112-5). Thus injuries may result from the fall and impact with other horses. Falls may result in fatal fractures of the cervical or thoracolumbar vertebrae. Rib fractures usually result from a fall and may cause severe lameness and/or respiratory signs. Other fractures seen commonly, usually resulting from a fall, include scapular, radial, and humeral fractures; fractures of the accessory

Fig. 112-5 • Horse no. 12 is about to be brought down by a fallen horse and jockey.

carpal bone; and fractures of the lateral malleolus of the tibia. Major muscle ruptures, especially in the hindlimbs (e.g., semimembranosus, quadriceps, or adductor) also usually result from a fall. Rupture of the fibularis tertius may occur if the horse falls with forced hyperextension of the hock.

A significant statistical correlation exists between certain factors and the incidence of injury on racetracks:

- Increased firmness of the going results in an increased injury rate in all forms of National Hunt racing.
- Increased incidence of injury on firm ground is further increased by increasing the length of the race.
- In hurdle races run over more than 2½ miles with only a few obstacles (six to eight), the casualty rate increases compared with the same distance with nine or more fences.
- Races ridden by amateur riders carry a higher risk of serious injuries.

Digital flexor tendon lacerations frequently are sustained as horses race over fences and generally occur on the palmar aspect of the metacarpal region, proximal to the proximal sesamoid bones (PSBs). It is important to recognize that the site of a skin laceration may not coincide with the site of a tendon laceration.

Some important injuries occur more commonly during racing than training. Luxation of the SDFT from the tuber calcanei sometimes occurs. Rupture of the musculotendonous junction of the superficial digital flexor (SDF) muscle is an unusual injury, but is an important injury in steeplechasers. SDF tendonitis is common in National Hunt horses,⁵⁻⁷ and recurrent injuries may result in complete rupture of the tendon.

CONFORMATION AND LAMENESS

With an increasing proportion of National Hunt horses starting training earlier and running first on the flat at 3 years of age and then over hurdles at 4 years of age, the trend has been toward using smaller, lighter-framed horses. Although such horses are not necessarily more prone to injury, they seem less able to cope with deep, holding going often encountered in the winter months compared with the more traditionally bred rangy National Hunt store horses, which are often rather late maturing.

For a National Hunt steeplechaser or hurdler to race until 10 years of age is not uncommon, so the racing career is considerably longer than for a European flat racehorse. Horses should be well balanced and proportioned, with good feet and adequate bone for body size and weight. Horses with back-at-the-knee conformation, carpus valgus, offset knees, or substantial toed-in or toed-out conformation particularly may be predisposed to forelimb problems. A long back may be associated with an increased risk of back problems. A horse with straight hocks or long, sloping hind pasterns may have an increased risk of hindlimb lameness.

In a study evaluating variation in conformation in a cohort of National Hunt horses, Thoroughbreds were found to be different from other breeds in lengths, joint angles, and deviations, but variation was small.⁸ In a group of 108 National Hunt horses an increase in intermandibular

width, flexor angle of the shoulder joint, and coxal angle (angle between the ilium and ischium) had a positive effect on race performance.⁹ Performance decreased with increases in girth width and hind digit length and with valgus conformation of the metacarpophalangeal joint, and the risk of superficial digital flexor tendonitis increased with increased metacarpophalangeal joint angle and carpus valgus limb deformity.⁹ The risk of pelvic fracture decreased with an increase in coxal angle, but risk increased with greater tarsus valgus limb deformity.⁹

LAMENESS EXAMINATION

Diagnosis of lameness starts with a full history, which should include stage of training, because, for example, a 6-year-old store horse starting training is as susceptible to stress fractures as an immature athlete. The clinician should establish whether the horse has run recently. Is the lameness of recent onset, or is it a chronic problem that has been getting progressively worse? Some trainers request advice as soon as lameness is recognized, whereas others may restrict the horse to light work and seek veterinary advice only if lameness persists. Some trainers treat a lame horse with phenylbutazone. Many trainers are happy for horses to come out rather short, shuffly, and stiff and warm up to move more freely; however, more overt lameness usually supervenes, or a back problem develops secondarily.

It is important to determine if the horse has had any time off recently with the present trainer or a previous trainer that may suggest a previous injury. There may be a history of warmth associated with the palmar metacarpal region that, if the horse has been subsequently rested, may not be obvious on clinical examination. Does the horse have any history of trauma? Jumping history is also important: did the injury occur while the horse was schooling over fences or in a race? Did the horse fall or collide with another horse (Figure 112-6)? Does the lameness resolve with rest or does the horse warm out of lameness?

If the horse had a history of a fall, it is important to establish how the horse fell. It may be possible to review video footage. Did the horse turn a full somersault, land on its pelvis, and develop lameness thereafter? A pelvic injury should be suspected. Did the horse fall at the end of a 3-mile race on heavy going and lay winded? Information from the racecourse veterinarian may be particularly useful.

If a horse has a history of poor jumping performance, trying to establish if the horse has ever been a good jumper over hurdles or fences is worthwhile. Many of these horses are lame. The veterinarian needs to find out how the horse is jumping. Does the horse stand off the fences or jump flat? If a horse does not want to take off, it may have a hindlimb problem. If the horse jumps flat, it may have a back problem. If the horse is reluctant to land, it may have a forelimb problem.

If a horse is presented for evaluation for poor performance, it is important to try to assess the orthopedic component. About 50% of horses with poor performance are lame. When did the horse last race, and over what ground conditions? Did the jockey make any comments when he dismounted? Has the horse coughed? Is rectal temperature routinely monitored? Routine hematological

Fig. 112-6 • A fall at the Chair at the Grand National. The horse pitches steeply and lands on its neck.

examination and measurement of fibrinogen, comparing results with a baseline for that horse, are useful for detecting systemic abnormalities. Endoscopic examination of the upper airways and trachea, combined with a tracheal wash, are useful screening tools to eliminate a respiratory component to the problem.

The clinical examination does not differ from a routine lameness evaluation of any other type of horse, but because many horses have chronic problems with which they have been living until more obvious lameness supervened, the entire horse should be assessed, not just the postulated lame limb. In view of the high incidence of SDF tendonitis and suspensory desmitis, particular attention should be paid to the palmar metacarpal soft tissues. If the horse has a history of a fall while jumping, particular attention should be paid to the neck, back, and pelvic regions.

A thorough clinical examination may reveal palpable abnormalities in the palmar metacarpal region, evidence of effusion, or pain on flexion of a particular joint. Skeletal pelvic asymmetry or muscle wastage over the quarters also may be evident. Back and pelvic reflexes and the tone of the back and pelvic muscles should be assessed. Is any evidence of guarding apparent? Abnormal shoe wear may give clues about which limb or limbs are lame, which is otherwise not always easy to determine in a horse moving short because of pain in several limbs.

Dynamic examination at the walk and trot in a straight line, followed by flexion tests, should be followed by examination on firm and soft going on the lunge at the trot and canter. The horse should be turned tightly to the left and to the right. If a history of a fall exists, a complete neurological examination should be performed.

If a horse is lame after a recent fall, the investigative approach depends on the degree of lameness and the rate of improvement. A horse with a pelvic injury is usually

very lame initially, although lameness associated with an ilial wing fracture usually improves substantially within 24 hours. Lameness associated with an ilial shaft fracture is usually persistent, and the horse remains extremely lame. These horses should be crosstied, assuming the horse's temperament is suitable. Some ilial wing fractures can be detected with ultrasonography, but the diagnosis of others requires nuclear scintigraphy. Nuclear scintigraphy may give false-negative results if done before 5 to 7 days after injury. If a horse shows only mild to moderate lameness after a recent fall, the horse generally is allowed rest for 7 to 10 days and is then reassessed, and only if lameness persists is further investigation carried out.

DIAGNOSTIC ANALGESIA

If no obvious cause of lameness is apparent, then diagnostic analgesia is performed, but no particular differences in approach exist for this type of horse. However, if clinical signs suggest an intraarticular problem, such as synovial effusion and pain on passive manipulation of a joint, then intraarticular analgesia of the suspect joint may be performed first. If intraarticular analgesia is carried out, clipping a small area is preferred, but some trainers are reluctant to allow this, and provided that the hair coat is not excessively long, a timed 5-minute surgical scrub is performed before injection.

If a fracture is suspected based on the history or clinical signs, diagnostic analgesia is not performed. A horse that pulled up lame on the gallops or finished work and then became severely lame while walking home may have a stress fracture. Stress fractures of the third metacarpal bone (McIII), the third metatarsal bone (MtIII), and the tibia are common. If a stress fracture is suspected, the horse is examined radiographically or scintigraphically.

If soft tissue swelling is identified clinically, then ultrasonography is performed routinely as the next diagnostic step.

IMAGING CONSIDERATIONS

Radiography is performed routinely using standard radiographic images. Special images at different angles may be required for demonstrating specific lesions, based on the preliminary examination. Some stress fractures are difficult to identify radiologically, and if a fracture is suspected on clinical grounds, radiographic examination is repeated 10 to 14 days later.

If the clinician suspects an abnormality of the palmar metacarpal soft tissues, an ultrasonographic examination should be performed. In view of the high incidence of bilateral lesions, both limbs should be examined routinely. A systematic approach is essential, focusing on the SDFT, deep digital flexor tendon, and suspensory ligament (SL) in turn. It is almost invariably necessary to clip the metacarpal and metatarsal regions to achieve satisfactory image quality, because most National Hunt horses have thick guard hairs. However, satisfactory images of the pelvis usually can be obtained after washing with chlorhexidine for about 10 minutes, soaking with alcohol, washing off (to avoid alcohol-induced damage to the transducer), and liberally applying coupling gel.

Transverse and longitudinal images of the metacarpal and metatarsal regions are required to gain a full appreciation of the severity of injury. An injury index giving a quantitative assessment of damage can help in communication with trainers and may help to convince them of the clinical significance of an injury associated with only mild clinical signs. Each structure should be evaluated sequentially from proximally to distally at predetermined measured intervals (4 or 5 cm) distal to the accessory carpal bone or each zone should be examined (see Chapter 16). Cross-sectional area (CSA) or circumferential measurements are made at comparable sites in each limb. Measurement of the size of damaged fibers is also useful. One author (RvP) describes the severity of a core lesion by multiplying the percentage of CSA of the tendon damaged by the length of the lesion and by the percentage of the fibers damaged within the injury (assessed visually). For example, a core lesion that occupies 10% of the CSA of the tendon, extends 10 cm proximodistally, and is assessed visually as having 75% of the fibers within the core lesion damaged has an index of $10 \times 10 \times 0.75 = 75$. A similar lesion occupying 30% of the CSA has an injury index of $30 \times 10 \times 0.75 = 225$. All images should be recorded routinely for future comparisons.

Nuclear scintigraphy is indicated as a screening tool when a lame horse is presented after a bad fall, particularly when a moderate-to-severe lameness has persisted for more than 3 or 4 days. Scintigraphy also may be indicated if severe, sudden-onset lameness occurs with no localizing clinical signs to rule out fracture before a dynamic workup is contemplated. Scintigraphy often is more rewarding in horses with acute injuries than those with chronic lameness. Scintigraphy usually can be targeted to specific areas such as the pelvis or both hindlimbs unless the horse has lameness involving several limbs. During evaluation of the pelvis, radioactive urine in the bladder can confound

interpretation. The use of furosemide may help, but this drug may make the horse fidgety, and catheterization of the bladder, followed by flushing with warm water, may be preferable.

PROCEEDING WITHOUT A DIAGNOSIS

National Hunt horses have a longer career than flat racehorses, and less prize money is available to be won. Therefore the pressure to get a horse sound quickly often is less, and many trainers accept resting the horse if a diagnosis cannot be achieved by the techniques described previously. However, an attempt to reach a diagnosis always should be made.

SHOEING CONSIDERATIONS AND LAMENESS

Most National Hunt horses train and run in light steel shoes with one toe clip in front and two side clips on hind shoes. Some trainers change to a hind shoe with a single toe clip for racing. Good shoeing is essential. Given the high incidence of foot problems causing lameness, a good relationship with a skilled farrier is invaluable. Poor foot conformation, especially low collapsed heels, may predispose the horse to SDF tendonitis. Bar shoes combined with a rolled toe often are used for horses with collapsed heels. If a foot is conformed poorly, the risk exists of shoes being pulled off repeatedly in training, particularly if the branches of the shoe are set too far medially or laterally.

THE TEN MOST COMMON CAUSES OF LAMENESS IN STEEPLECHASERS, HURDLERS, AND POINT TO POINT HORSES

1. Superficial digital flexor tendon injuries
2. Suspensory ligament injuries
3. Lameness associated with the carpus
4. Lameness associated with the hocks
5. Lameness associated with the pelvis
6. Lameness localized to the feet
7. Fractures of the third metacarpal bone; pelvic and tibial fractures
8. Lameness localized to the metacarpophalangeal joints
9. Traumatic injuries, particularly of the back and neck, after falls
10. Back problems

DIAGNOSIS AND MANAGEMENT OF LAMENESS IN STEEPLECHASERS, HURDLERS, AND POINT TO POINT HORSES

Superficial Digital Flexor Tendonitis

Epidemiological studies have demonstrated a 16% to 43% incidence of SDFT injuries in National Hunt horses, with some reports but not all studies documenting variations among trainers (10% to 40%).^{7,10,11} Although most of the injuries occur in the forelimbs, hindlimb injuries also occur. Horses 5 years old or younger were less at risk, whereas the maximum injury rate was seen in horses 12 to 14 years of age.⁹ Many trainers routinely assess forelimb

SDFTs daily, and some are adept at detecting relatively subtle lesions. Veterinary involvement may enhance these skills. Many, but not all, trainers are keen to have ultrasonographic assessment of suspected tendon injuries. Some trainers tend to ignore suspicious injuries at the end of a season, contrary to veterinary advice. This may be one reason why a peak incidence of tendon injury tends to occur at the beginning of the season when horses start galloping after a short summer break. Other horses may have been kept in training late in the season to get an extra race and may have sustained injury, which may or may not have been manifested clinically. A second peak incidence of injuries tends to occur at the end of the season, perhaps related to races run on faster going. SDF tendonitis is more common in steeplechasers than in hurdlers, but this may reflect the older population of the horses rather than the type of racing itself. The degree of lameness at the time of acute injury may reflect the severity of tendon damage.

Horses with acute lesions are managed with aggressive antiinflammatory treatment for 5 days, including systemic nonsteroidal antiinflammatory drugs (e.g., phenylbutazone and eltenac), with or without a single dose of corticosteroids (e.g., dexamethasone), and cold hosing several times daily. Cold water bandages or cold kaolin is applied to the limbs. Some thin-skinned horses are prone to blistering, so any bandaging must be done with care. Other popular proprietary poultices, such as Animalintex (Robinson Animal Health Care, Chesterfield, United Kingdom) and a variety of clay-based preparations, may irritate small unnoticed wounds and are therefore avoided.

An initial ultrasonographic examination is performed about 7 days after the injury is first recognized. Horses with central core lesions may be treated by decompression, using needle fenestration or a fixed blade. This is performed with the horse sedated and with use of regional analgesia. Follow-up ultrasonographic examinations frequently are performed 3 to 4 weeks after injury, because the preliminary examination may underestimate the degree of damage because of ongoing enzymatic degradation. This gives a baseline scan for the injury.

Many differing views are given on the best management of SDF tendonitis in National Hunt horses. Adequately rehabilitating a tendon that was injured late in a season so that the horse can race the following season without a disproportionately high risk of reinjury is difficult. Firing remains a popular treatment, and because many owners and trainers are prepared to rest a horse for 12 months after firing when they would not give such a long convalescent period if rest alone was recommended, this treatment still is carried out widely. Nonetheless, the reinjury rate remains high, so many alternatives have been tried with various success. These alternatives range from at least 9 months of field rest, intralesional injection of hyaluronan, polysulfated glycosaminoglycan, a phenol derivative, β -aminopropionitrile fumarate, platelet-rich plasma, or growth factors, combined with a variety of exercise regimens. Intralesional β -aminopropionitrile fumarate combined with a strictly controlled exercise program has produced good results in selected horses (RvP, SJD) but is no longer commercially available; however, the time for return to racing often is prolonged, in part dictated by the time of injury and the seasonal nature of racing.

The average time to return to racing was 17 months. Preliminary results with cultured mesenchymal stem cell injections indicate that recurrent injury rate after treatment may be reduced compared with other treatments.¹² The reinjury rate in the injured or contralateral limb 2 years after returning to full work was approximately 33% in 83 horses treated with mesenchymal stem cells¹² compared with 55% of 28 horses managed conservatively or with β -aminopropionitrile fumarate.¹³ Forty-two percent of horses treated with mesenchymal stem cells were still racing 2 years after returning to full work.¹² The owner or trainer must be committed to at least 3 to 4 months of walking exercise after treatment, and some horses are unsuited to this temperamentally, unless a horse walker is available. Regardless of the methods of management, a slow, gradual rehabilitation before resumption of ridden work seems beneficial. Ideally the horse should be walking on a horse walker daily for 3 months before resuming ridden exercise. The horse can be turned out during this 3-month period. A cage horse walker in which the horse is free and in which the speed can be set manually to encourage the horse to walk briskly is best.

Serial ultrasonographic examinations are particularly useful as exercise is resumed—about 1 month after walking begins, then again before cantering commences, and a third time before fast work commences. Commonly as work intensity increases, small hypoechogenic areas develop, especially in areas in which the fiber pattern is not parallel. In some horses these lesions disappear, provided the horse is maintained at the same exercise level, whereas in others a core lesion redevelops, and the trainer should be warned accordingly.

The prognosis is related partly to the severity of injury.¹⁴ In a follow-up study of 73 National Hunt and point to point racehorses, lesions were graded by ultrasonography as mild (<50% CSA or <100 mm in length), moderate (50% to 75% CSA or 110 to 160 mm in length), or severe (>75% CSA or >160 mm in length). All mildly affected horses returned to training, and 63% raced. Fifty percent of horses with a moderate lesion resumed training, and 23% raced. However, only 30% of horses with severe lesions resumed training, despite up to 6 months longer convalescence, and 23% raced. The mean reinjury rate of those resuming work was 40% in the period of follow-up (9 to 30 months).

The type of racing in which the horse is involved may influence the prognosis for return to racing after SDF tendonitis. Fifty-one (73%) of 70 hurdlers raced five or more times after desmotomy of the accessory ligament of the SDFT for treatment of tendonitis compared with 39 (58%) of 67 steeplechasers.¹⁵

Cellulitis, skin necrosis, and necrosis of the underlying SDFT are poorly understood conditions that have been recognized in National Hunt horses (SJD) and flat race horses that have run over long distances (>1½ miles) (RvP). Many horses run in boots or exercise bandages, which are removed after racing. Whether exercise bandages would be on long enough to cause pressure necrosis is debatable. The typical history is that a proprietary claylike substance (Kaolin, Ice-Tite) or commercial poultice (e.g., Animalintex) is applied to the metacarpal regions after racing, with or without overlying bandages. The applied substance is removed the following day. Clinical signs may be apparent within 24 to 72 hours, with the development of

peritendonous edema and serum ooze, progressing to skin slough and slough of deeper tissues, which may take several weeks. The degree of damage varies among horses, and one or both limbs may be affected. One author (SJD) has seen this unassociated with SDF tendonitis, whereas another (RvP) often has seen concurrent SDF tendonitis. The prognosis depends on the depth of the lesions. One author (RvP) recommends that horses be thoroughly cooled after racing before anything is applied topically to the limbs, to minimize the risks of these complications. If a SDFT injury is suspected, then the advice of the course veterinarian should be sought.

Suspensory Desmitis

Suspensory desmitis is a major problem in National Hunt horses, especially steeplechasers and point to point racehorses.^{3,10,11} However, in a study of 1119 horses in training followed over two seasons, SDFT lesions were more common (1.71/100 horse months in training) than SL injuries (0.23/100 horse months).¹¹ Injuries of the body or branches occur in forelimbs and hindlimbs, sometimes with a fracture of the distal third of the second metacarpal bone (McII) or second metatarsal bone (MtII), fourth metacarpal bone (McIV) or fourth metatarsal bone (MtIV), apical or abaxial proximal sesamoid fractures, or sesamoiditis. Proximal suspensory desmitis does occur in forelimbs and hindlimbs and is recognized more commonly in hindlimbs, but the true incidence may be underestimated.

Body and branch injuries of the SL often go unrecognized until the ligament is grossly enlarged; possibly some of these are cumulative injuries rather than single-event injuries. More careful monitoring of the SLs by regular palpation with the limb not bearing weight may lead to earlier detection of important lesions. The degree of swelling sometimes makes it difficult to palpate accurately the distal end of the McII and the McIV.

Assessment of structural damage is done by ultrasonography in a way similar to that described for SDFT lesions. Lesions are assessed acutely (up to 7 days after injury and 4 to 6 weeks later) to determine the baseline degree of injury. Some of the swelling contributing to the apparent swelling of a SL branch is often a periligamentous reaction. Radiographic examination is necessary to evaluate the McII or the MtII, the McIV or the MtIV, and the PSBs.

Body and branch injuries are associated with a prolonged convalescence irrespective of the way in which they are managed, and returning to racing often takes longer than for a horse with SDF tendonitis. The rate of recurrent injury is high. Surgical removal of fractures of the McII or the McIV (or the MtII or the MtIV) has little bearing on the horse's final outcome.

Conservative management of rest alone, splitting the SL, intralesional injections of β -aminopropionitrile fumarate, and pin firing have been used with no clinically significant differences in outcome. There is anecdotal evidence that mesenchymal stem cell treatment or platelet-rich plasma may improve healing and reduce reinjury rate.

Lameness Associated with the Carpus

Synovitis and OA of the middle carpal joint are common and are treated by intraarticular injection with hyaluronan, with or without triamcinolone acetonide. A horse with synovitis may be treated more conservatively than a flat

racehorse when the pressure is great to maintain the horse in training if at all possible. With a young National Hunt horse with a career of several years ahead, restricting the horse to walking exercise until clinical signs have resolved fully often is more prudent.

Chip fractures of the dorsal border of any of the carpal bones are common and often are associated with preexisting OA. Treatment is by surgical removal of the fragment(s), and prognosis depends on the degree of OA; most horses are able to return successfully to racing. Slab fractures of the third carpal bone are also common but are not always associated with obvious clinical signs. Lameness is often mild and associated with only slight effusion of the middle carpal joint.

Accessory carpal bone fractures usually result from a fall and are common in National Hunt horses. Most fractures are longitudinal (vertical) and occur midway between the dorsal and palmar borders of the bone, but less commonly articular chip fractures occur on the proximal or distal dorsal articular margin. The latter must be removed surgically; otherwise, severe OA ensues. Horses with the more common longitudinal fractures do not require treatment other than prolonged rest. Some fractures heal only by fibrous union, but the prognosis for return to racing is good. Some horses have effusion in the carpal sheath when work is resumed, which responds well to the intrathecal administration of triamcinolone acetonide and for which retinacular release is seldom necessary.

Lameness Associated with the Hock

The degree of lameness caused by hock pain varies, and lameness is more commonly unilateral, unlike the bilateral lameness usually seen in the flat racehorse. The most common cause is osteoarthritis (OA) of the distal hock joints, although traumatic injuries also occur. The horse may adduct the lower limb as the leg is brought forward at the walk and trot. The lameness often worsens after flexion and when the lame limb is on the inside on the lunge. More subtle signs of poor jumping or back pain may herald a problem originating in the hocks.

Lameness most often is alleviated by intraarticular analgesia of the tarsometatarsal joint. It is rare to have to inject the centrodistal joint as well, despite the variable communication between the joints and the fact that osteoarthritic changes seen radiologically often affect both joints. Radiography of the hocks should include four standard views, because radiological changes may be visible only on one projection. Abnormalities range from mild periarticular osteophyte formation to osteolysis, with narrowing of the joint spaces, with or without periarticular new bone. Occasionally, young horses in the first year in training have clinically significant radiological changes in one limb. The damage was probably present before onset of training and may be associated with collapse of the distal tarsal bones or a traumatic incident earlier in the horse's life.

Care should be taken when interpreting scintigraphic images of the hocks in National Hunt horses. Often areas of increased radiopharmaceutical uptake (IRU) are seen but do not appear to correlate with clinical signs of lameness. Treatment of horses with OA of the distal tarsal joints usually consists of intraarticular medication of the tarsometatarsal joint with combinations of hyaluronan and corticosteroids. Consideration should be given to chemical

fusion of painful distal hock joints in young National Hunt horses.

Traumatic injuries involving the hock are common. Injuries frequently sustained after a fall include fracture of the lateral malleolus of the distal aspect of the tibia and tearing of the attachments of the collateral ligaments. The lameness in horses with lateral malleolar fractures can be mild, and lesions may be missed if radiography is not carried out. Ultrasonography may be more useful than radiology for the early diagnosis of collateral ligament injury. Follow-up radiology some weeks later may reveal some entheses new bone formation. Horses with these injuries have a good prognosis for a return to racing, although improvement in lameness may be slow. Some debate exists about the optimal management of horses with lateral malleolar fractures: conservative or surgical. Both treatments carry favorable prognoses. Surgical removal is usually easiest by making an incision directly over the fracture fragment(s) rather than by attempting arthroscopic removal. Arthroscopic surgical techniques can be used successfully, particularly if motorized equipment such as a synovial resector is available to improve visibility and help with dissection of ligamentous attachments (Editors).

Lameness Associated with the Pelvis

Lameness associated with the pelvis in the National Hunt horse is more likely to result from a traumatic incident than a stress fracture. Falls or poor landings while jumping (see [Figure 112-4](#)) may lead to subluxation of the sacroiliac joint or pelvic fractures. However, ilial stress fractures also occur, especially in horses entering training at 5 years of age or older. A strong correlation between pelvic lameness and working horses on loose all-weather surfaces, especially on unmanaged wood chip surfaces and particularly uphill, has been noted (AS, RvP). In a study of 1119 horses in training followed over two seasons there were 111 fractures, 17% of which were pelvic fractures.¹¹

Clinical signs can vary from severe lameness with obvious crepitus to mild stiffness. It is important to examine the pelvis per rectum when pelvic damage is suspected. A horse with an ilial fracture sustained during a fall may be lame initially and improve rapidly within 48 hours. If an ilial wing fracture is nondisplaced, the horse could return to cantering exercise before lameness recurs. Muscle spasm may result in substantial asymmetry of the tubera coxae in the acute stage, but this usually also resolves within 24 hours. Severe lameness associated with an ilial shaft or acetabular fracture is invariably persistent. Ilial stress fractures may cause only mild clinical signs, and sometimes the most important abnormality is shortening of the contralateral forelimb stride as the horse moves off from standing still. This gait abnormality rapidly resolves.

Fractures of the ilial wing involving the dorsal surface often can be diagnosed by ultrasonography, but incomplete stress fractures involving the ventral aspect cannot be seen.

Nuclear scintigraphy is invaluable for assessing pelvic pain. Assessment of pelvic fractures should be delayed for at least 5 to 7 days after injury to avoid false-negative results. If scintigraphy indicates IRU in the region of the coxofemoral joint, obtaining numerous oblique scintigraphic images is worthwhile to try to assess whether the

fracture involves the joint. Other scintigraphic changes seen include IRU at the greater and third trochanters of the femur associated with damage to the insertions of the deep and middle gluteal tendons and the superficial gluteal insertion, respectively.

Horses with nondisplaced ilial wing fractures have a good prognosis, whereas the prognosis for those with fractures of the ilial shaft¹⁶ or ilial fractures involving the acetabulum is poor.

Lameness Associated with the Front Feet

Lameness associated with the front feet may vary from a shortened gait to obvious lameness. The most common causes of foot lameness include solar bruising, corns, and subsolar abscesses. Other commonly recognized causes of foot lameness in the National Hunt horse include pedal osteitis, palmar foot pain, and fractures of the distal phalanx. Palmar foot pain may be caused by bruising of the heel bulbs or may be caused by deeper pain associated with the deep digital flexor tendon or navicular bone, with a much poorer prognosis. Horses that train on downland are particularly at risk for bruising of the feet or penetrating injuries of the sole caused by flints. The latter may result in infectious osteitis of the distal phalanx. Protective aluminum pads may prevent solar penetrations but do not prevent bruising, because the pad is distorted and puts pressure on the sole if a horse stands on a flint.

In horses with chronic lameness associated with foot pain, local analgesia, radiography, and ultrasonography sometimes can be unrewarding or give equivocal results. Nuclear scintigraphy using soft tissue and bone phase images is sometimes helpful. Magnetic resonance imaging is increasingly useful.

Fractures of the Third Metacarpal and Metatarsal Bones

The most common long bone fractures in National Hunt horses are condylar fractures of the McIII (or the MtIII) and pelvic and tibial fractures. In a study of 1119 horses followed in training over two seasons, there was a total of 111 fractures, 17% of which involved the McIII or the MtIII.¹¹ Former store horses were more at risk of fracture than former flat racehorses, although this difference was not significant. Fractures of the MtIII frequently involve the medial condyle and may spiral proximally. Full evaluation of the fracture may require numerous oblique radiographic images of the MtIII. Such fractures are more common in hurdlers than in steeplechasers. With prompt surgical treatment by internal fixation, the prognosis is good. Compound, comminuted fractures of the distal aspect of the McIII and the MtIII may occur during racing and may be associated with luxation of the fetlock. These horses have a guarded prognosis for return to racing.

Incomplete proximal palmar cortical fatigue fractures of the McIII occur commonly, especially in horses older than 4 years of age entering National Hunt or point to point training for the first time. Preexisting increased radiopacity in the proximomedial aspect of the McIII detected when lameness is first recognized in some horses suggests that abnormal bone modeling has existed for some time, subclinically or without clinical signs being recognized. Lesions are often bilateral. Lameness is characterized by

the horse becoming lamer the farther it trots and then improving if walked a few steps. Usually no localizing clinical signs are apparent, and diagnosis depends on localizing pain to the proximal palmar metacarpal region and identifying radiological lesions or scintigraphic evidence of increased bone turnover, in the absence of ultrasonographic abnormalities of the proximal aspect of the SL. Treatment of 3 months of rest with a graduated return to work is usually successful, and recurrent injury is unusual.

Less commonly, transverse stress fractures of the distal metaphyseal region of the McIII cause acute-onset lameness. No localizing signs may be apparent, but lameness is alleviated by a four-point nerve block of the palmar and palmar metacarpal nerves. Usually preexisting callus formation is evident on the distal metaphyseal region of the McIII on the dorsal or palmar aspects.

Lameness Associated with the Metacarpophalangeal Joint

Most lameness associated with the metacarpophalangeal (fetlock) joint is degenerative. Fetlock lameness is often present bilaterally with a shortened forelimb gait, warmth around the joint, and reduction of range of motion. Flexion often exacerbates lameness. Lameness often is improved by intraarticular analgesia of the metacarpophalangeal joint. Radiography may reveal periarticular osteophytes or a small fragment on the dorsoproximal border of the proximal phalanx. If the PSBs and SL attachments are involved in sesamoiditis, a low palmar or four-point nerve block is required to alleviate lameness. New bone formation and osteolysis may occur on the abaxial surface of the PSBs at the attachments of the SL. This form of sesamoiditis more commonly is associated with damage to the attachments of the SL onto the PSB rather than a primary PSB disease and is seen much more frequently in National Hunt horses than other types of horses. The condition is related to the stress to which the palmar metacarpal soft tissues are subjected during jumping and galloping.

Treatment options include the following:

1. Injection of the fetlock joint with hyaluronan, with or without corticosteroids
2. Arthroscopy and removal of any free fragments
3. Blistering of the palmar aspect of the fetlock to treat sesamoiditis

The prognosis for lameness affecting the fetlock is more guarded in the National Hunt horse than in the flat racing horse but such lameness occurs much less frequently.

Neck Lesions

Neck trauma usually results from a fall (see [Figure 112-6](#)) and is more common in steeplechasers and point to point racehorses than in hurdlers.²⁻⁷ Neck trauma may result in ataxia or a stiff neck, with or without forelimb lameness, and can cause death. Ataxia may be transient or persistent. Radiographic examination should be performed if ataxia or neck pain and stiffness persist for more than a few days. Fractures in the cranial or midneck regions are most common, but occasionally fractures occur caudally, which may be difficult to assess without a fixed, high-output x-ray machine. Nuclear scintigraphy can be helpful in localizing

such fractures, but false-negative results in the caudal cervical spine are possible. Horses with persistent ataxia have a guarded prognosis. Most horses with a fracture unassociated with ataxia can return to racing despite residual neck stiffness.

Back Pain

Back pain in the National Hunt horse may be primary or may develop secondary to chronic lameness in one or more limbs and is being recognized with increasing frequency. Nuisance problems include the development of seromas underneath the saddle, which are probably attributable to an ill-fitting saddle and poor riding. Most trainers regularly use a physiotherapist, who may be the first person asked to look at a horse that is not right. Only if the horse fails to respond to one or two treatments, or if the physiotherapist recognizes obvious lameness, is veterinary advice sought. A good working relationship with the physiotherapist is valuable, because without a doubt the rehabilitation and long-term management of horses with chronic back pain can be helped by regular physiotherapy treatment. Moreover, certain findings on palpation have been shown to predict the occurrence of some pelvic and hindlimb fractures.¹⁷ However, the veterinarian should have responsibility for both the diagnosis and the development of the treatment program.

Knowledge of back problems in National Hunt horses has increased greatly with more routine use of nuclear scintigraphy. Thorough investigation of the back is warranted in horses with chronic back pain, with a history of jumping awkwardly (see [Figure 112-1](#)), or after bad falls. Physical examination of the back often can be unrewarding concerning specific diagnosis, because the examination may reveal only stiffness and pain on palpation. Underlying problems such as active kissing spines (impinging, overriding, or overlapping dorsal spinous processes) or OA of the synovial intervertebral articulations (facet joints) are common in National Hunt horses and can be ruled in or out using scintigraphy and radiography. In a horse with an acutely sore back after a fall, scintigraphy can be used to determine if any bony damage occurred. The clinician should bear in mind that falls may involve more than one horse, and a fallen horse may get shunted (pushed) by one behind. Serious vertebral fractures can produce nothing more than severe stiffness and guarding in some horses after a fall, if the spinal cord itself is not compromised. For example, scintigraphy may reveal intense focal IRU suggesting a fracture in the region of the second or third lumbar vertebra. Radiology may demonstrate an obvious change in orientation of the spinous processes at this level, without being able to demonstrate a fracture. Lateral and dorsal scintigraphic images are useful to identify fractures of the transverse processes of the lumbar vertebrae.

Ultrasonographic examination is also useful for identifying some soft tissue injuries such as desmitis of the supraspinous or dorsal sacroiliac ligaments.

Horses with traumatic injuries often respond well to prolonged rest combined with physiotherapy. Horses with kissing spines often improve after local infiltration with corticosteroids.

Successful management of chronic back pain needs a broad approach. Many National Hunt horses have an inadequate jumping education and poor technique (see

Figure 112-1). Traditionally in the United Kingdom and Ireland, horses learn to jump by loose schooling over small fences; horses are schooled ridden over two or three small fences, once or twice when they are fresh. In France horses often are trained to jump out of deep going, when they are tired, providing a better grounding for racing conditions. The standard of riding of the work riders is often only moderate, and employing some staff with a background of working with event horses or show jumpers may be beneficial. Time should be spent teaching the horse to jump properly. Often more time is available in the summer break period to devote to such problems.

Additional work from the field, or keeping the horse in work, or bringing the horse in early should be advised. The horse should be encouraged to work in a round outline by exercising in draw reins to improve the development of the epaxial muscles. The horse can be given a warm-up period on a horse walker before being ridden. Use of a well-fitting hunting saddle rather than a racing saddle should be encouraged. After exercise the horse may benefit from being led home from the gallops rather than ridden.

Other Injuries

National Hunt horses seem particularly vulnerable to lacerations involving the distal palmar (plantar) aspect of the metacarpal (metatarsal) region, which may involve the SDFT or the digital flexor tendon sheath (DFTS), usually resulting from the horse being struck or from penetration by a sharp stone. Such horses with these injuries should be treated early and aggressively, especially if the DFTS is involved. With early lavage of the DFTS using an arthroscope, combined with intravenous broad-spectrum antimicrobial treatment for 5 to 7 days, the prognosis is usually excellent unless substantial damage of the SDFT has occurred.

A high number of complex injuries to the palmar (plantar) soft tissues of the pastern have been seen in National Hunt horses as sequelae to previous SDF tendonitis in the metacarpal region or as primary injuries. Although injury to one or both branches of the SDFT may occur alone, simultaneous injuries of the oblique and straight sesamoidean ligaments are not uncommon. The prognosis for horses with such injuries is generally guarded.

THE TEN MOST COMMON CAUSES OF LAMENESS IN TIMBER RACING HORSES

1. Superficial digital flexor tendonitis
2. Suspensory desmitis
3. Osteoarthritis of the distal hock joints
4. Thoracolumbar or pelvic pain
5. Distal sesamoidean desmitis
6. Osteoarthritis of the metacarpophalangeal joint
7. Soft tissue trauma of the stifle
8. Interference injuries during racing
9. Timber shins
10. Fracture of the patella

DIAGNOSIS AND MANAGEMENT OF LAMENESS IN TIMBER RACING HORSES

Lameness falls into three groups: acute injury or breakdown after racing, chronic wear injury caused by the horse's age and length of competitive career, and traumatic injuries caused by interference from another horse or hitting a fence.

Eighty-five percent of acute injuries after racing are caused by SDF tendonitis and SL desmitis. Many timber horses have had previous SDFT injuries from earlier flat racing. The long courses (up to 4 miles), variable turf quality and terrain, fatigue, and poor weather conditions predispose horses to injury. Injuries range from small tears to catastrophic breakdowns that may necessitate humane destruction. Regular clinical and ultrasonographic monitoring is useful for detecting subtle changes and for making recommendations about running on specific footing (ground) conditions (KK).

Once recognized, horses with OA of the metacarpophalangeal and the distal hock joints require management, because increased lameness may be induced by the increased work leading up to a race. Keeping horses as comfortable as possible throughout training is preferable, which may necessitate intraarticular medication two or three times during a season, using hyaluronan for the metacarpophalangeal joints and hyaluronan and corticosteroids for the distal hock joints (KK). Orally administered glucosamine and chondroitin sulfate are used commonly. It is important to keep the horse well shod and to use cold hydrotherapy after strenuous exercise.

Traumatic injuries sustained during racing are common, with the hindlimbs particularly vulnerable because of the horse hitting fences at speed. Damage to the quadriceps muscles, periarticular soft tissues of the stifle, and stifle joint is common, although determination of the severity of injury is usually easiest several hours after a race rather than immediately. Radiological examination is indicated to rule out a patellar fracture, which requires surgical management. Bruising of the patellar ligaments is common, with or without effusion of the femoropatellar joint, and is treated by drainage of excess synovial fluid and injection of hyaluronan (4 to 6 mL) combined with controlled exercise and nonsteroidal antiinflammatory drugs.

Timber shin describes firm enlargement of the dorsal aspect of the metatarsal region because of chronic bruising of the long digital extensor tendon, with fibrosis of the tendon and peritendinous soft tissues. Timber shin is unsightly and is not associated with long-term lameness, but recent trauma results in lameness from severe swelling of the leg, with pain on protraction.

Injuries sustained by interference from another horse, for example, traumatic heel bulb laceration or strike injuries on the palmar or plantar aspect of the fetlock, are common (see other injuries on this page). Injuries also can result from falls—for example, fracture of the accessory carpal bone—or from a galloping horse treading on a faller.

The Finnish Horse and Other Scandinavian Cold-Blooded Trotters

Kristiina Ertola and Jukka Houttu

HISTORY OF THE BREEDS

The Finnhorse is the only original horse breed in Finland. Sweden and Norway also have similar cold-blooded breeds. The Finnhorse has been known for about 1000 years and originally was used for farm and forest work and in the army. The Stud Book of the Finnhorse was founded in 1907 for draft and carriage horses but is now divided into four parts for racing trotters, riding horses, draft horses, and small pony-type horses. Seventy-five percent of the registered Finnhorses are trotters. The Finnhorse is heavy and well muscled, with a short neck and usually a heavy head. The average height is 155 to 160 cm, but pony-sized Finnhorses exist. Swedish and Norwegian cold-blooded horses are slightly lighter and smaller than Finnhorses, with an average height of 150 to 160 cm.

Trotting competitions are the main use of Finnhorses. In Scandinavia all harness races are for trotters; there are no pacing races. The first records of trotting races are from 1817, when races were arranged on the ice of the river Aura in Turku. The first races with official timing took place in 1862 in Viipuri. In the early years the trotting races were arranged by the state to support and develop horse breeding in Finland. In the first races the distance was 2138 m, and they were on a straight track. The horses raced individually, and prizes were given according to the times. The first official Finnish record was from 1865 by the mare Brita. The average time for 1000 m was 1.51.3 (1 minute 51.3 seconds, equivalent to a mile in 2 minutes 59 seconds). Today the record is held by Viesker and is 1.19.9 (2:08.5). Betting was first introduced in 1928 but developed slowly until the 1960s, after which rapid growth followed.

In Sweden, racing also was started in the early nineteenth century on roads and icetracks. The first permanent tracks were built in the early twentieth century. The first official record in Sweden was in 1829, 1.37.6 (2:37), held by a Norwegian horse, Sleipner Varg. Today the record is 1.17.9 (2:05) by a Swedish stallion, Jarvsofaks. When racing became more popular, Swedish and Norwegian horsemen started trading horses across the border, and the Swedish and Norwegian breeds began to merge together. Today the breeds are genetically alike, and they now are considered to be the same breed. Sweden and Norway have a close collaboration in breeding and racing, and their horses race in the same races.

Today the races are held at modern dirt tracks, and in the same events there are separate races for Finnhorses and

Standardbreds (STBs). The Finnhorses are allowed to race first at the age of 3 years, but not uncommonly they start racing as late as 5 or 6 years of age. They are allowed to race until 16 years of age, and a Finnhorse usually is considered to be best from 7 to 10 years of age. Some stakes races are held for 4- and 5-year-olds, but the main events are for older horses. The biggest event for Finnhorses is the Kuninkuusravit, the Royal Trot, which is held annually in July or August at a different track in Finland each year. The race is one of the major sporting events in Finland, attracting about 50,000 people. Separate races are held for mares and stallions; geldings are excluded. To be allowed to race in the Kuninkuusravit, the horse has to be approved for public breeding and has to be entered in the Stud Book, which requires inspection and approval by a special board. The horses race three times in 2 days over distances of 1609 m, 2100 m, and 3100 m, and the final result is based on the total time for all three races. To win the royal title is the greatest honor a Finnhorse can ever achieve; the best stallions have won the title five times (Vieteri, Vekseli, and Viesker), and the best mares, four times (Suhina and Valomerkki). This is good proof of stamina and endurance, which are typical for the Finnhorse at its best.

In Sweden and Norway horses usually start racing at 3 years of age and are allowed to race until the age of 15. Stakes races are open to Swedish and Norwegian horses, and big races are held for 3- and 4-year-olds and for older horses. Finnish horses are not allowed in these races, and only a few races are held in which all Scandinavian horses race together.

TRAINING A COLD-BLOODED TROTTER

Traditionally the horses have been bred and trained by farmers, and many remain home bred and trained. There are no sales for Finnhorses, Swedish, or Norwegian trotters. Most horses are broken at 2 years of age, spend the next summer at pasture, and then start more serious training in the winter at 3 years of age, often with a summer break. Farm and forest work has historically been part of the training to build up strength. Speed work is not done at all at this stage, and traditionally some trainers have never used speed work. Horses started racing at 5 to 6 years of age and raced themselves to condition. However, many professional trainers now train cold-blooded horses, and the horses are better prepared for the races and start racing younger. The race times for the beginners are faster, which has caused problems for many old-school trainers. Many Finnhorses are not natural trotters, and building them up to speed takes time and training. If fast speeds are demanded too early, gait abnormalities develop at higher speeds, and horses lose complete control of the trotting action while appearing sound at a slower trot.

Training cold-blooded trotters takes much more time than for STBs, making training more expensive and leading to problems in getting new owners and trainers. In all Scandinavian countries, fewer cold-blood races are held than STB races, and they are concentrated in the north. Nonetheless, cold-blood racing is supported by the central racing organizations of each country and continues to thrive.

Fig. 113-1 • Winter racing. (Courtesy Olavi Ilmonen, Lahti, Finland.)

RACETRACKS AND WEATHER CONDITIONS

The racetracks in Scandinavia are 1000-m oval dirt tracks, and the horses race counterclockwise. The climate is cold in the winter, and the tracks freeze and get covered by snow (Figure 113-1). In winter temporary tracks also are made on ice for smaller races with no betting. The variable climate causes track problems. In late autumn when the track is frozen but not yet covered by snow, the surface can be treacherous. Snowfall makes the tracks smooth but not hard, and provided the horse is shod properly, the track is not slippery. In the springtime, when the snow begins to melt, the track conditions vary throughout the day, being hard in the morning after a night frost, becoming good for a few hours when the frost melts, and then becoming wet and soft the rest of the day. Keeping the track in good condition requires much skill.

Because of the long winter, much of the training has to be done on snowy or icy surfaces. Snow is a good surface on which to train a horse, but special shoeing with studs is essential so that the horses do not slip. In the winter many trainers do much of the speed work in snow, which can be deep. The training speeds can be lower because of the resistance, but the training effect is equal or even better than when the training is done on the track. Snow provides a soft and smooth surface, acting as a shock absorber. Many horses with lameness problems race better in winter because of the training in snow. Horses also are trained on the ice of lakes, which is also a good surface. The surface of the ice gives slightly, and shoes with studs can get a good grip. The worst training surface is ground that is frozen hard like asphalt; this type of surface causes many lameness problems.

SHOEING CONSIDERATIONS

In the winter (November to April) special requirements for shoeing are needed to prevent the horses from slipping on ice. Studs, 5 to 15 mm in length with sharp tips that offer a good grip on the ice or snow, are screwed into the shoes. Four to 15 studs are used per shoe; more studs usually are

used in the hind shoes. It is important to have enough studs for the horse to avoid slipping slightly at every step, causing joint and muscle soreness. A risk of interference injuries exists, and some horses with poor action cannot race in the winter. Forelimb heel injuries are common if a horse breaks stride. Elbow boots may be necessary to protect the elbows from stud-induced trauma. Some lameness problems get worse during the winter, because traction from the studs stops the feet abruptly. Hock-related lameness is often worse during the winter, and tendon and suspensory ligament (SL) problems increase.

The shoeing of racing Finnhorses is otherwise much like that of STBs, but many Finnhorses are not natural trotters and tend to gallop or pace, so many trainers use special shoeing to help the horse to balance. Young horses often need heavy front shoes with toe weights and bell (over-reach) boots when they are learning to trot. The total weight per foot can be up to 500 to 800 g, and this predisposes the horses to lameness, particularly tendon and SL injuries. Improvements in breeding have decreased the number of horses with severe balancing problems. On the hind feet Finnhorses usually wear normal STB shoes. The lateral branch of the shoe is often longer and bent slightly outward (trailer) to make the hind action wider and therefore avoid interference between the forelimbs and hindlimbs. Although many STBs race unshod, this is rare in Finnhorses.

CONFORMATION AND LAMENESS

The Finnhorse is a heavy, draft-type horse compared with other racehorses. The forehead is heavier than the rear of the horse and is combined with a heavy head and a thick and short neck, causing much stress to the forelimbs. Finnhorses often stand back at the knee, and this sometimes is combined with lateral deviation of the carpus (offset knees). Forelimb tendon, SL, and carpal injuries are not uncommon. The hindlimbs are usually conformed better in Finnhorses than the forelimbs. The most common faults are sickle hocks and cow hocks, which can cause curbs or other lameness problems in the tarsal area. Fetlock conformation is often good, and most Finnhorses have big hooves with good-quality horn.

LAMENESS EXAMINATION

Many Finnhorses complete a racing career without serious lameness problems and require substantially less veterinary treatment than STBs, perhaps because of slower racing speeds. The lameness examination for a Finnish horse is similar to that for a STB racehorse, and similar problems occur. Clinical history is particularly important, and the following questions should be asked:

1. How long has the horse been in training, and how has it been trained? What is the duration of lameness, and has the horse ever trotted sound at high speed? A Finnhorse often develops slowly and has to be taught to trot. Therefore many action problems in young horses are not caused by lameness but by lack of coordination. Lack of strength or condition may predispose horses to lameness.
2. Does the horse trot straight? Is the horse hanging on a line? Is the horse hanging on a shaft? Does the

horse need sidepoles or headpoles? A great many lameness problems show only at higher speeds, especially in the early stages of the problem. This is particularly true with hindlimb lameness. With right hindlimb lameness the horse's rear end usually turns to the left shaft, and the horse hangs on the right line. Correspondingly, problems in the left hindlimb cause hanging on the left line and turning the rear end to the right shaft. A horse with bilateral lameness may move straight. With forelimb lameness this tendency to be on a line is less obvious.

3. Does the horse trot better in turns or on straightaways? In which direction are the turns better? In a counterclockwise direction, horses with right hindlimb lameness are usually worse in the turns. Horses with left hindlimb lameness are worse in the straightaways and usually are worst in the turns in a clockwise direction.
4. Is the horse better on soft or hard surfaces? Sidebones often cause lameness on hard surfaces, as do many other foot problems.
5. Is the horse worst when it starts to trot? Does the horse warm into or out of the lameness problem? In young horses (4- to 5-year-olds), bilateral hind fetlock pain is a common cause of lameness, resulting in a short hindlimb stride when first trotting. The lameness usually improves if the horse is jogged for about 1000 to 3000 m.
6. Do the studs in the shoes affect the lameness in the winter? Many horses with carpal or tarsal lameness are worse with studs.

The veterinarian should assess the type and use of the horse and its conformation, muscular development, and general condition and should systematically palpate all the limbs, because concurrent lameness in several limbs often occurs.

Many horses are trained with sleighs in the winter and are harnessed with collars. If the collar is not fitted properly, it can cause shoulder musculature soreness. Soreness of the shoulder or scapular musculature also can point to other problems in the forelimbs, especially when the lameness is bilateral. Inflammation of the carpal sheath is common because of the heavy front of Finnhorses and the conformation of the carpi and invariably is associated with palpable distention. Proximal suspensory desmitis (PSD) sometimes occurs, and pain may be induced by palpation of the proximal metacarpal region.

The second (McII) and fourth (McIV) metacarpal bones in Finnhorses are sometimes thick and prominent, but this is not usually relevant (Figure 113-2), although thick metacarpal bones are sometimes seen in horses with PSD or tenosynovitis of the carpal sheath. Ossification of the cartilages of the foot usually can be felt by thickening and loss of elasticity in the region of the coronet, but pain is seldom evident on palpation.

In the hindlimbs special emphasis needs to be given to palpation of the tarsus. Tarsal pain is common in Finnhorses with poor conformation. Curbs are common in younger horses (3 to 6 years of age), and distal hock joint pain is common in older horses. The Churchill test works well in Finnhorses. Stifle lameness is not common in Finnhorses, and upward fixation of the patella is rare. Osteochondrosis of the lateral trochlear ridge of the femur occurs

Fig. 113-2 • Dorsomedial-plantarolateral oblique radiographic image of the metacarpal region. The second metacarpal bone is enlarged, which usually has no clinical significance.

occasionally in foals and young horses, sometimes with large defects that respond poorly to arthroscopic debridement.

The gait and response to flexion tests can be evaluated properly only when the horse is calm and well controlled by the handler. It is essential that the horse trots straight and not too fast. Many horses are too eager and excited and need to be sedated or tranquilized mildly for flexion tests. Acepromazine (0.01 to 0.025 mg/kg) or romifidine (0.01 to 0.03 mg/kg) is suitable. Sedation is especially important for Finnhorse stallions, which are often difficult to handle, and sometimes two leaders are necessary to control the horse and keep it trotting straight. Horses used for riding can be examined in a circle on the lunge, but trotters are seldom taught to lunge.

When flexion tests are performed, it is essential for the veterinarian always to examine all limbs and not only those that are suspected to be lame. The tests always should be done in a similar manner and order. When doing flexion tests, the clinician should note all reactions. We do not think false-positive reactions exist, only reactions of different grades. The clinician needs to collect all the information and decide which reactions are clinically significant. Proximal and distal limb flexion tests are done separately in the forelimbs and hindlimbs, using a force of approximately 40 kPa for 60 seconds.

In general, all the trotting Finnhorses also are examined at the track at high speeds. Many action problems, especially in the young horses, show only at high speeds. The horse is harnessed in a higher sulky than normal, so the driver of the vehicle does not obscure the horse. The veterinarian drives a car behind or beside the horse at the racetrack. Examining the horse from the car is more helpful than driving the horse, because the clinician can be some distance away from the horse to see the action more clearly, and abnormalities can be assessed more easily.

Diagnostic analgesia is used as in STBs. The clinician must keep in mind that high-speed lameness seldom can be resolved totally by analgesic techniques. Every block changes the horse's action, and when the veterinarian does several blocks on the same horse, assessing the meaning of each block is difficult. When examining a horse with high-speed lameness, the clinician must believe what vision, touch, and experience indicate.

IMAGING CONSIDERATIONS

In Finnhorse trotters, radiological changes are found much less commonly than in STBs. Carpal chip fractures are rare in Finnhorses, and sclerosis of the third carpal bone is unusual. Osteochondrosis is also rare in the Finnhorse, though the prevalence has been increasing slightly in the past decade. Because osteochondrosis is unusual, radiographic examination of young Finnhorses is not performed routinely if clinical signs are absent. Controlling osteochondrosis in Finnhorses is attempted by obtaining radiographs of all stallions that are proposed for public breeding. Stallions with osteochondrosis generally are not accepted. Ossification of the cartilages of the foot is a common radiological finding in Finnhorses. Navicular disease is a rare diagnosis. Enlargement of the McII and the McIV is common and often does not cause clinical signs. Flakelike fragments adjacent to the McII usually result from interference.

Ultrasonography is invaluable for assessing soft tissue injuries and may be more useful than radiography in examining the splint bones, because splint bone problems often are associated with carpal canal syndrome or PSD.

UNDIAGNOSED LAMENESS

Some young trotting Finnhorses trot soundly at slow speeds and show no signs of lameness during a lameness examination, but when asked for speed, the horses lose the action completely. Loss of rhythm causes this; the horse simply cannot trot at higher speeds. This often happens to talented horses that have early speed with little training but do not have the strength to maintain it. The training regimen must be aimed at building strength, especially in the hindlimbs. Horses are trotted in 1- to 3-minute intervals with resistance from a special resistance cart, in deep snow, or uphill. Training takes a long time, sometimes up to a year, until these horses learn to trot again, and some horses never recover. Because the main racing events are for aged horses, time is not as big a factor for Finnhorses as for STBs. It is quite possible for a horse to recover completely and become a top-class racehorse at an older age.

TEN MOST COMMON CAUSES OF LAMENESS

1. Carpal conditions
2. Tarsal conditions
3. Superficial digital flexor tendonitis
4. Suspensory desmitis
5. Curb
6. Ossification of the cartilages of the foot
7. Splints
8. Metatarsophalangeal joint pain
9. Tenosynovitis of the digital flexor tendon sheath
10. Loss of rhythm

LAMENESS CONDITIONS TYPICAL OF FINNHORSES

Carpal synovitis is common in Finnhorses, and signs are similar to those seen in STBs. In the early stages a horse warms out of lameness quickly. Often horses with carpal problems begin to roll over and may try to pace or gallop instead of trotting. The horse may trot if the shoes are weighted more, but this may accentuate the primary problem. Without treatment the lameness worsens, and the horse begins to hang on a line and gradually becomes overtly lame. Radiological changes rarely are seen, probably because of the slower racing speeds compared with those of Thoroughbreds and STBs. Treatment consists of intraarticular medication with hyaluronan, polysulfated glycosaminoglycans (PSGAGs), or corticosteroids, alone or in combination, together with rest for several weeks. Recently the use of autologous conditioned serum (ACS) has been increasing in treating joint lameness with good results.

Carpal canal syndrome is also common in Finnhorses, sometimes simultaneously with carpalitis, sometimes on its own. Ultrasonography is useful for confirming the diagnosis. The treatment is usually rest combined with intrathecal administration of hyaluronan or corticosteroids. Some horses do not respond to conservative therapy, and surgical treatment using tenoscopy may be necessary. Osteochondromas of the distal caudal aspect of the radius are seen tenoscopically, often accompanied by lesions of the deep digital flexor tendon (DDFT). The severity of these osteochondromas is difficult to assess radiologically, and often the diagnosis is made by tenoscopy. Surgical removal of the osteochondroma and debridement of torn fibers of the DDFT result in a good prognosis for racing.

Tarsal lameness is common in Finnhorses and is the most frequent cause of hindlimb lameness, usually because of distal hock joint pain. Mild lameness in horses is not noticed easily at slow speeds, but with increasing speed the horse begins to drag the affected limb, and the rear end moves to the opposite shaft. The horse usually hangs on the line on the side of the affected limb. Radiological evidence of osteoarthritis may or may not be apparent. Radiological changes are seen less frequently than in STBs. Intraarticular treatments with corticosteroids, hyaluronan, or PSGAGs are used widely. Treatment with intravenous (IV) tiludronate is often beneficial. In some horses cunean tenectomy can be useful.

Superficial digital flexor (SDF) tendonitis and suspensory desmitis are common. SDF tendonitis usually occurs in forelimbs, and poor conformation or overweighting the shoes may be predisposing factors. In the hindlimb, tendon injuries are usually traumatic. Suspensory desmitis occurs more frequently in forelimbs than hindlimbs, probably because of the heavy front conformation. Suspensory branch injuries are most common.

Finnhorses cope better with chronic suspensory desmitis than do STBs because of the lower racing speeds, longer rest periods, ability of the horses to race at an older age, and thus better opportunities to heal. Suspensory desmitis is sometimes associated with splint bone fractures or exostoses.

Treatment of Finnhorses with SDF tendonitis and suspensory desmitis is most often conservative, with long rest

Fig. 113-3 • Transverse ultrasonographic image of the plantar distal aspect of the hock. Medial is to the left. There is extensive subcutaneous heterogeneous echogenic material (arrows) plantar to the superficial digital flexor tendon in a horse with curb.

periods. Tendon splitting or desmotomy of the accessory ligament of the SDF tendon (SDFT) sometimes is used for tendonitis. Hot firing has been a traditional treatment for Finnhorses with tendonitis and desmitis for many decades, and some veterinarians still use it in some horses, though with mixed success. Stem cell treatments are used as in other breeds.

Curbs (soft tissue enlargement in the plantar tarsal and proximal plantar metatarsal regions) often are seen in young horses (3 to 5 years old) in early training, especially those with sickle hocks (see Chapter 78). Curbs seldom cause spontaneous lameness. Usually the signs show first at higher speeds, when the cranial phase of the stride in the affected limb is shortened, and the horse begins to drag the limb. Ultrasonographically, peritendonous and periligamentous inflammation is the most common finding (Figure 113-3). Injuries of the SDFT or the DDFT are rarely seen. Most veterinarians treat horses with curbs symptomatically, without ultrasonographic examination to determine the structure involved. Treatments include rest, corticosteroid or dimethyl sulfoxide injections, or pin firing. Cryotherapy is not used as widely as pin firing. The prognosis with all treatments is very good.

Ossification of the cartilages of the foot (sidebones) is a common finding in the front feet of heavy horses, occurring in 80% of Finnhorses. The condition is more common in females than in males and positively correlates with the size of the horse. The grade of the ossification is usually mild, but extensive ossification sometimes occurs. The cause is unclear, but a heritable component exists. In a recent study evaluating ossification of the cartilages of the foot in 964 Finnhorses, females had more ossification than males, and this difference increased with age.¹ The ossification in the medial cartilages progressed significantly with age in females but not in males, and in lateral cartilages the increase in ossification with age was evident in both sexes.¹ Estimates of heritability for the ossification parameters varied slightly between the cartilages as well as between the front feet.¹ For total ossification, the estimates of heritability varied from 0.31 (right lateral) to 0.50 (left

medial) and were slightly higher for ossification at the base of the cartilages.¹ High genetic correlations were found for total ossification between the medial and lateral cartilages in the foot and for parallel ossification parameters between the right and left feet.¹ The authors concluded that the estimates of heritability were relatively high, and both cartilages and front feet have a similar genetic tendency to ossify.¹ The cartilages start ossifying at an early age, unassociated with training of the horse. Other contributory factors may include hoof conformation, shoeing, and concussion.

The clinical relevance of sidebones is questionable. Most horses with mild or moderate ossification show no clinical signs. Ossification is detected only by radiology. With extensive ossification the cartilages are palpable proximal to the coronary band. Palpation does not induce pain. In general, horses with large sidebones show some clinical signs, especially on hard ground. Lameness at slow speeds is rare, but at high speeds with increased concussion the forelimb stride is shortened and the horse breaks to pace or gallop. In a study of 21 Finnhorses with ossification of the cartilages of the front feet, there was no significant relationship between height of the ossifications measured radiologically and increased radiopharmaceutical uptake (IRU) in the cartilages of the foot. Separate centers of ossification were not associated with IRU.² Intense IRU was seen unilaterally in four horses, medially in one horse, and laterally in three. In two of these horses a unilateral palmar digital nerve block relieved the mild lameness.² In the other two horses no obvious lameness was seen, but both had a history of being stiff or having locomotion problems during high-speed trot.² In two horses with IRU in the lateral cartilage of the foot, an incomplete fusion line was found radiologically between a large separate center of ossification and the base. The third horse had extensive ossification with bony protrusions, suggestive of chronic enthesopathy in a narrow foot.² In all cartilages of the foot with intense IRU and/or lameness, the ossified part of the cartilage was wider and more irregular compared with other ossifications.² The authors concluded that IRU and a different radiological appearance of affected cartilages from that of unaffected cartilages within the same horse were definite signs of clinical relevance. Obscure locomotion problems were more commonly associated with ossification of the cartilages than true lameness.²

The diagnosis is confirmed radiologically, using dorso-palmar images. Osteoarthritis of the distal interphalangeal joint and navicular disease may cause similar clinical signs and may be present concurrently with sidebones.

The treatment options are limited, because the condition persists. Shoeing with egg bar shoes, often combined with thick pads, is helpful in some horses. Most horses with sidebones can race with moderate-to-good success when shod properly and raced only on good surfaces. Because of the hereditary background, all Finnhorse stallions that are used for public breeding have to be free of sidebones, radiologically, before being accepted.

Splints are fairly common in the forelimbs of young, growing horses, and affected horses are usually treated conservatively with rest. Most splints resolve spontaneously, but local corticosteroid injections or cryotherapy sometimes is used. Interference injury may result in a

flake of bone detached from the McII. These fragments do not heal with rest and horses respond poorly to corticosteroid injections or cryotherapy. Surgical removal is usually necessary.

Chronic tenosynovitis of the digital flexor tendon sheath (DFTS) is a common cause of lameness in aged cold-blooded trotters and usually develops gradually, with mild or moderate swelling and no lameness for long periods. In time the DFTS becomes fibrotic, and masses and adhesions develop. At this stage constriction by the palmar annular ligament (PAL) may occur. Many horses can perform well despite chronic tenosynovitis, especially in hindlimbs. Intrathecal administration of hyaluronan, with or without corticosteroids, is used for horses with acute tenosynovitis. Frequent corticosteroid injections often seem to increase tenosynovial masses. Physiotherapy and especially shockwave therapy are often beneficial in treating Finnhorses with chronic tenosynovitis, not only for controlling pain but also for helping to keep the DFTS as elastic as possible. Tenoscopy and transection of the PAL is used if the condition is advanced. Cold-blooded horses with chronic tenosynovitis seem to respond more poorly to treatment than do STBs with similar lesions. This may be because Finnhorses are often older and of greater weight.

In young Finnhorses, bilateral hindlimb fetlock pain is fairly common and causes a short and stiff hindlimb stride when they start to trot, which improves with exercise early in the condition. When both hind fetlocks are blocked simultaneously, the action changes completely. Pain is considered to be associated with subchondral bone remodeling of the distal aspect of the MtIII. A variety of treatments have been used, including shockwave therapy, joint lavage, and intraarticular treatment with PSGAGs, hyaluronan, or corticosteroids, often combined with parenteral administration of NSAIDs. In some Finnhorses IV tiludronate infusion is more beneficial than intraarticular treatments. If lameness is severe, surgical drilling of the subchondral bone is performed. Horses remain lame for several months, but the long-term prognosis is reasonable.

Osteochondrosis is rare in Finnhorses, but when it does occur, osteochondrosis most often is seen in the cranial aspect of the intermediate ridge of the tibia and causes effusion of the tarsocrural joint. Treatment is removal of the fragment(s) by arthroscopy. The femoropatellar joint is another typical predilection site for osteochondrosis in Finnhorses, and osteochondrosis of this joint causes clinical signs in young horses. Finnhorses with large defects of the lateral trochlear ridge of the femur have a guarded or poor prognosis.

Nonracing Sports Horses

| Chapter 114

Prepurchase Examination of the Performance Horse

Richard D. Mitchell and Sue J. Dyson

The purchase or prepurchase examination is a much discussed and sometimes feared subject for equine practitioners. Careless conduct and poor documentation can leave veterinarians wishing they had not agreed to perform the examination, whereas forethought and good planning can lead to a rewarding experience for the practitioner and the client. In the United States the examination is referred to as the *purchase examination*, because in many cases the deal already has been completed, whereas in Europe the examination usually is referred to as the *prepurchase examination*, because generally the purchaser has agreed to buy the horse subject to a satisfactory veterinary examination. In some countries (e.g., Holland), where many horses are sold through professional dealers, a horse may be purchased by the dealer and then examined by a veterinarian on behalf of the dealer before resale within a few days. In Europe young competition horses may be sold at auction and are subjected to a prepurchase examination before the sale.

The terms of sale usually permit a purchaser to have an additional independent examination performed within a predetermined time after the sale.

GOALS OF THE EXAMINATION

When requested to evaluate a horse for purchase, the veterinarian should keep several goals in mind. First, the examination should be an objective assessment of the horse's physical condition. Second, the examination should be a fact-finding mission to aid the purchaser in his or her decision to make a purchase. This may involve the veterinarian in making some predictions based on experience and probability, but care must be taken to be factual and objective. Last, the examination can serve as a formal introduction to a horse for which the practitioner may provide long-term care. Such relationships may affect the veterinarian's decision-making process relative to a client's needs.

It is helpful to have knowledge of the disciplines for which the horse has been and is to be used. Various equine sports place differing demands on the horse, and the clinician should be aware of sometimes subtle, yet important, differences. Some physical characteristics or conditions may be acceptable for certain levels of performance but not acceptable for others. For example, a previous strain of a superficial digital flexor tendon (SDFT) may be an acceptable risk for a show hunter but may carry a high risk for an event horse. Veterinarians should avoid performing

prepurchase examinations on horses that will be involved in disciplines with which they are not familiar.

The veterinarian needs to discuss the goals of the examination and horse ownership with the prospective purchaser. Understanding the client, the trainer, and what is expected of the horse will help the veterinarian in assessing the horse's potential suitability. Passing or failing the horse is not the veterinarian's job, but it is his or her role to advise on how existing conditions may affect the future use of the horse. It is therefore self-evident that prepurchase examinations should not be performed by recent graduates, who may be fully competent in performing clinical examinations but generally do not have the experience of how to interpret the findings of the examinations and are not in a position to evaluate risk. The prospective purchaser requires advice about the risks of proceeding with the purchase. Prior knowledge of clients, their expectations of the horse, and their attitude toward risk make offering such advice easier, compared with clients about whom clinicians know little.

A veterinarian must be open-minded and should consider himself or herself to be a facilitator for the sales contract: the vendor wishes to sell the horse, the purchaser may have searched for a long time to find a suitable horse, and the veterinarian's role is to enable the transaction to take place if such is reasonable. Nonetheless, the veterinarian must be streetwise and recognize that a minority of unscrupulous vendors may try to misrepresent a horse. *Caveat emptor*. Veterinarians also should be aware that prospective purchasers often are keen to buy horses and in their enthusiasm may wish to overlook any problems that are identified during the examination. A veterinarian who believes that the risks of buying a horse are too high is responsible for trying to dissuade the purchaser from proceeding further. If the purchaser ignores the advice, it is essential that the veterinarian documents adequately his or her observations and advice. Purchasers can have remarkably selective memories when things start to go wrong.

The scope of the examination can range from a comprehensive clinical examination of the horse, using basic powers of observation, to a complex investigation using advanced techniques such as radiography, ultrasonography, endoscopy, thermography, scintigraphy, and magnetic resonance imaging (MRI). The wishes of the buyer are important in determining the extent and depth of the examination, which also must be dictated to some extent by the value of the horse and its future athletic expectations. Some consideration to cost should be given, but not at the cost of the quality of the examination. The veterinarian should allow some latitude for deciding what is needed to answer questions posed by the clinical examination.

CONTRACT

A veterinarian enters a business arrangement with a purchaser when he or she agrees to perform a prepurchase examination. It is imperative for the veterinarian to understand the buyer's intentions for the horse and the expectations of the proposed examination. The terms, details, and costs of the examination should be discussed at the time of the initial request. The extent and depth of the examination and its limitations should be emphasized.

This is straightforward when the veterinarian is dealing directly with the purchaser, assuming that the purchaser has knowledge of horses. The terms of agreement become more difficult when a veterinarian is speaking to an agent for the potential owner or to the prospective rider of the horse, when the actual purchaser has no knowledge of horses. Such persons may have expectations of the horse as if it were a mechanical object like a car.

Purchaser's Reservations

The veterinarian is responsible for the following:

1. Establishing whether the purchaser has any reservations about the horse.
2. Determining whether the horse has been in regular work until the examination.
3. Warning the client of the hazards of performing an examination on a horse that has not been in regular work; previous lameness or back problems may be inapparent until the horse is in regular work. It may be helpful to suggest that the purchaser check the horse's official competition record to determine whether any unexpected breaks from competition have occurred.

Purchase for Resale

If the horse is to be purchased for resale, this should be noted. The purchaser should be warned that the clinician's interpretation of the findings may not be identical to that of another veterinary surgeon. The examining veterinarian may regard the horse as a reasonable risk for purchase, but this is not a guarantee that others have the same opinion. All observations should be well documented so that comparisons can be made should questions arise at a subsequent resale examination. Such notes may well help save a sale in the future and save face for the initial veterinarian.

Insuring the Horse

It is important to establish if the horse will be insured for loss of use for a specific athletic activity or for veterinary fees. The purchaser should be advised that the examining veterinarian may consider the horse a reasonable risk for purchase but that does not necessarily equate with the horse being a normal insurance risk. The veterinarian may consider that a small, well-rounded osseous opacity on the dorsal aspect of the distal interphalangeal joint is unlikely to be of clinical significance, but for an insurance company to place an exclusion on problems related to the joint would not be unreasonable. The veterinarian should advise the purchaser that if such problems arise, the purchaser should communicate with the insurance company before completing the purchase transaction.

Blood Tests and Limitations

The client should be informed clearly that the results presented are good for the day of examination, but predictions about future soundness and suitability are impossible. The limitations of analysis of blood for drugs must be detailed, bearing in mind the difficulties of detection of many drugs administered by the intraarticular route. The client should be warned that several days may elapse before the results of blood tests are known and that the purchase transaction should not be completed until the results are known. The

veterinarian should discuss with the client how the findings will be transmitted and what kind of report will be issued.

Conflicts of Interest

Any potential conflicts of interest for the veterinarian must be disclosed to the buyer. Previous dealings with the vendor, although the vendor may not be a current client, could be perceived as a conflict of interest. In the horse world today, not to have such conflicts arise is difficult, but such conflicts should be acknowledged, and the buyer should be given the option of having someone else perform the examination.

COMMUNICATION WITH THE VENDOR

The vendor must understand clearly what facilities are required for the examination and should be advised that the horse should be stabled before the examination and not worked earlier in the day. If the vendor is unable to be present at the examination, the veterinarian should establish the answers to a number of important questions in advance:

1. How long has the horse been in the owner's possession?
2. Is the horse in regular work?
3. Has the horse had any previous lameness?
4. Has the horse had any previous medical problem?
5. Is the horse receiving any medication, or has it done so in the last 8 weeks?
6. Does the horse have any vices (crib-biting, wind sucking, box walking), or does it bite or kick?
7. Has the horse been seen to shake its head?
8. Has the horse had previous surgery?
9. Does the horse normally live in or out?
10. Does the horse have dry or soaked hay or a haylage preparation?
11. When was the horse last trimmed or shod?

Ideally vendors should sign a copy of their responses to these questions (Figure 114-1).

When the examination actually is performed, ideally all involved parties or their agents should be present. This provides an environment in which the veterinarian can ask pertinent questions of the buyer and seller regarding the horse's history and future use and can assure the buyer that a complete examination has been performed. Problems that arise during the examination can be discussed with the purchaser.

The veterinarian should not compromise the standard of the examination because of physical conditions. If modifying the procedure of the usual examination technique is necessary, such should be noted in the subsequent report, and the purchaser should be advised accordingly. The limitations of the conclusions drawn from the examination should be documented. If an uncooperative vendor or agent makes conducting the usual examination difficult, the veterinarian may choose not to continue the examination to protect the interests of the buyer and personal interests.

EXAMINATION AT A DISTANCE

A client may request the veterinarian to examine a valuable competition horse that is a long distance away or possibly

in a foreign country. A number of alternative strategies can be applied. It may be prudent to first have the horse undergo radiographic examination and proceed with visiting the horse only if these radiographs are considered acceptable. The veterinarian is of course relying on the honesty of everyone concerned that the radiographic images provided are current images of the horse in question. It is critical that the veterinarian provide clear guidelines of the views required and be prepared not to compromise on quality. Alternatively, the veterinarian can travel and examine the horse and be present for the radiographic assessment. However, this may mean that the clinical examination is compromised by inadequate riding facilities at a veterinary clinic or that substantial time is spent traveling between the site where the horse is examined and the veterinary clinic where ancillary tests are performed. However, clinic facilities may be required anyway for additional examinations such as ultrasonography or endoscopy.

A client may inform the veterinarian of an intended purchase of a horse from a foreign country and that it has been recommended that he or she employ a specific clinician from that country to carry out the prepurchase examination. The client should be warned that the method of carrying out and reporting the examination may differ from what he or she is used to seeing and may have limitations of which he or she is unaware. For example, in some countries in Europe the examination is much more limited and does not encompass assessment of conformation. It is not usual practice to examine the horse being ridden. It is worthwhile developing a group of professional colleagues whose clinical expertise and trustworthiness the veterinarian respects, one of whom can be recommended to the purchaser. The veterinary surgeon performing the examination should be requested to communicate with the client's own veterinarian and to send radiographs for assessment. Discussion between two colleagues—one who has examined the horse and the other who knows the client—can result in a highly satisfactory outcome.

CLINICAL EXAMINATION AT REST

Various national bodies have established guidelines for the way in which a prepurchase examination should be carried out and reported, to which the veterinarian obviously should adhere. The legal responsibilities for the veterinary surgeon and the vendor may vary in different countries. For example, in Holland the expectations of the veterinary examination performed on behalf of an amateur purchaser are higher than for a professional purchaser. In Denmark, if clinically significant radiological abnormalities that obviously predate the purchase are discovered soon after purchase, the vendor is liable.

The clinical examination should evaluate all organ systems as comprehensively as possible. The examination should be methodical and repeatable. Using a checklist may help. The principal aims of this chapter are to focus on the examination of the musculoskeletal and neurological systems^{1,2} and to discuss the interpretation of abnormal findings.

The veterinarian should identify the horse, including name, breed, sex, age, markings, tattoos, freeze marks, brands, and height. In Europe a freeze brand L signifies that

the horse has previously been a loss of use insurance case. The horse's identity should be compared with its passport or vaccination certificate.

The horse first should be examined in the stable, with assessment of demeanor, attitude, stance, and conformation and thorough observation and palpation of the head, neck, back, and limbs as described in Chapters 4 to 6. Collection of blood samples may be performed at this stage or when the examination is completed and the veterinarian deems that purchase will probably be recommended. More

comprehensive evaluation of the feet, overall conformation, and evaluation of muscle symmetry is best performed outside, where the horse can be viewed better from all angles.

If the horse will be used for show purposes, in which the cosmetic appearance of the horse is important, the veterinarian should draw the purchaser's attention to all possible abnormalities, such as a prominent base (head) of the fourth metatarsal bone that a lay judge may misconstrue as a curb. If the purchaser has expressed reservations

about a swelling such as a splint, the veterinarian should be sure to document its size and possible importance. If the purchaser is concerned about the horse's hock conformation, recommending radiographic examination of the hocks is worthwhile, even if the veterinarian considers the conformation to be acceptable and the horse appears sound.

Conformation

Although assessment of conformation as far as it may influence future lameness is considered an important part of the examination in the United States and United Kingdom, this is not usual practice, and in Holland, for example, is not included. It is important to recognize that breed differences in conformation exist and that what might be acceptable in one breed does not necessarily apply to others. The relevance of conformational abnormalities in part is dictated by the discipline in which the horse is involved.¹

Most Arabian horses have a short-coupled and slightly lordotic back; thus they are likely to have some degree of impingement of dorsal spinous processes. This is unlikely to compromise the horse's show performance. However, a dressage horse with a short back may well develop a clinical problem associated with impinging dorsal spinous processes when working at an advanced level. In such a horse the flexibility of the back at rest and when the horse is moving in hand and ridden must be assessed with great care, paying great attention to the freedom and elasticity of the gaits. Even if the horse is currently free of clinical signs, the purchaser should be advised that problems may occur in the future.

Young Warmblood breeds have a relatively high propensity for intermittent upward fixation or delayed release of the patella, especially those with a straight hindlimb conformation. Although the condition may be manageable in some, in others it can become a chronic problem, albeit a subtle one, resulting in low-grade discomfort and unwillingness to work. The veterinarian should observe the horse carefully as it moves over in the stable, to assess smooth or jerky movement of the patella on the left and right sides, and should check carefully for a surgical scar and the size of the medial patellar ligament, which if enlarged is likely to reflect a previous desmotomy or desmoplasty.

Very straight conformation of the hocks and abnormal extension of the hind fetlock joints are predisposing factors for and may be indicative of proximal suspensory desmitis and suspensory branch injury. The client should be advised of the potential importance of such findings and asked whether he or she wishes the examination to be continued. It may be preferable that the examination be terminated at this stage rather than the veterinarian running up a large bill and antagonizing the vendor by wasting more time.

The clinician should pay particular attention to the conformation of the feet and relate this to the type of ground surface on which the horse will have to work. A horse with flat feet and thin soles is not a good candidate for endurance riding. A horse with crumbly hoof walls is predisposed to losing shoes, and this can be disastrous for Three Day Event horses. Although changing the horse's nutrition and foot management may result in some improvement, accurate prediction of the degree of improvement that may be achieved is difficult. Sheared heels and

underrun heels in the forelimbs or hindlimbs may be primary problems or predispose horses to altered ways of moving, causing soreness in the more proximal parts of the limbs. These findings are particularly important in jumping and dressage horses and those used for cutting and reining.

The veterinarian should assess the forelimb conformation carefully from the front and ensure that the foot is positioned symmetrically under the central limb axis of the more proximal parts of the limb. A disproportionately high incidence of distal limb joint problems occurs in horses in which the pastern and foot are set more to the outside, with a tendency for the medial wall to become more upright and the lateral wall to be flared (Figure 114-2).

Many Warmblood breeds naturally have much narrower and upright foot conformation than other breeds. This predisposes the horses to develop thrush, and careful stable hygiene and foot cleanliness are necessary to control this problem. Asymmetry of front foot shape and size always should be documented and may reflect previous lameness in the limb with the more contracted foot, but it also may reflect development of a mild flexural deformity of the distal interphalangeal joint when the horse was a foal, which may be of no long-term relevance. The veterinarian should beware if the feet are long and misshapen; this finding may mask underlying conformational problems or asymmetry in foot shape and size. Postponing

Fig. 114-2 • Dorsal view of a forelimb with clinically significant conformational abnormalities. Medial is to the left. Note the position of the foot and pastern relative to the central axis of the metacarpal region (dotted line). The hoof capsule is distorted, and the foot shape is asymmetrical.

further assessment of the horse until the feet have been trimmed and shod properly may be preferable.

Some conformational abnormalities, such as over at the knee, do not appear to influence a horse's future soundness greatly but must be described. Failure to document observations leaves the veterinarian open to litigation if future problems arise.

Muscle Symmetry

Muscle asymmetry of the hindquarters may reflect previous or current hindlimb lameness, although it is not necessarily associated with future chronic lameness. Muscle asymmetry should alert the veterinarian to pay particular attention to the hindlimb gait in hand, on the lunge, and ridden and to the response to flexion tests. Asymmetry is an indication for flexion tests before and after ridden exercise. The potential clinical significance of muscle asymmetry must be discussed with the purchaser. Slight asymmetry of the tubera sacrale is a common finding and frequently is not of clinical significance. Nonetheless, the purchaser should be informed of its potential clinical significance.

Tendons and Ligaments

Particular attention should be paid to the size, shape, and stiffness of the tendinous and ligamentous structures of the metacarpal and pastern regions, bearing in mind that if the horse has sustained a bilateral tendon injury, both tendons may be enlarged slightly, and the clue to previous damage may be rounding of the margins of the tendons or abnormal stiffness. The clinical significance of a previous injury to the SDFT or suspensory ligament must be assessed in light of the horse's previous and future career. These injuries carry a high risk of recurrence in racehorses, event horses, high-level show jumpers, and endurance horses. However, the horse may perform satisfactorily as a hunter, a dressage horse, or a pleasure horse or at a low level in more demanding sports. The purchaser should be advised that further information about the repair of the injury may be obtained by ultrasonographic examination. Further information about when the injury was sustained and what the horse has done since then may be helpful. Decision making must be based on the athletic expectations of the horse, all other aspects of the horse's suitability, and whether the horse is being bought for resale. If the horse is a perfect schoolmaster for a junior rider and the price is reasonable, the risk/benefit ratio may be acceptable.

Assessment of Joints

Many horses have mild fetlock joint capsule distention or thickening. The relevance of distention must be assessed based on the environmental temperature: if it is cold, joint capsules are more likely to be tight than if it is warm. Asymmetry between left and right is of greater clinical significance than bilateral symmetry. The joints should be assessed carefully for any evidence of restricted range of motion or pain on manipulation. The range of motion varies among horses and is in part a reflection of age and work history, but asymmetry between left and right should be viewed with caution. The response to distal limb flexion and the horse's action on the lunge on a hard surface must be assessed carefully. Distention of the antebrachiocondylar or middle carpal joint capsules is rarely an insignificant

finding and even if unassociated with detectable lameness should prompt radiographic examination.

During hindlimb assessment, care should be taken to differentiate between pain on flexion of the proximal limb joints and reluctance to stand on the contralateral hindlimb, perhaps associated with sacroiliac pain. Abnormal limb flexion may be present if the horse is a shiverer. A high incidence of this condition occurs among high-performance Warmblood breeds, and it does not appear to compromise performance. However, an intending purchaser must be warned that the condition may be progressive and may make the horse difficult to trim and shoe.

Flexibility of the neck and back should be assessed, and the presence of any abnormal muscle tension or abnormal reaction to palpation of acupuncture trigger points should be noted. The veterinarian also should pay attention to the presence of sarcoids in a position where they may be abraded by tack. If a sarcoid is identified, the client always must be warned that such lesions may increase in number, but assuming that the client is aware of the risks, a small number of lesions at sites removed from the tack should not mitigate against purchase. The mouth should be examined carefully. Large hooks on the rostral aspect of the first upper cheek teeth are usually an indicator that large hooks also may be present on the caudal aspect of the lower caudal cheek teeth, which may be difficult to manage.

Sensation in the heel region of the forelimbs and the reaction to vigorous application of hoof testers should be assessed carefully to determine if a previous neurectomy may have been performed. The absence of a visible or palpable scar does not preclude previous surgery.

ASSESSMENT OF GAIT

The horse should be examined moving freely at a walk and trot on a firm surface, with particular attention directed to the stride length and lift to the stride relative to the horse's type. The veterinarian should bear in mind that a horse with a bilateral forelimb or hindlimb lameness may not appear overtly lame, but merely may have a slightly restricted gait. The veterinarian should beware of the situation encountered particularly in a professional's yard when the horse is encouraged by an assistant to trot excessively quickly, is unduly restrained, or is excessively fresh and trots crookedly. The horse must trot in a regular, relaxed rhythm with freedom of the head and neck; otherwise, lameness may be missed. The veterinarian should pay particular attention to how easily the horse turns when changing direction and the flexibility of the neck and back. If the horse trots in a particularly loose and extravagant way, the veterinarian should bear in mind that the horse may be mildly ataxic. Ataxia may not jeopardize a dressage horse when competing at lower levels, but when finer degrees of muscular strength and coordination are required in advanced dressage, performance may be compromised. The safety of a mildly ataxic horse jumping must be questioned. The veterinarian should watch the horse carefully as it decelerates, when signs of mild ataxia or jerky movement of the patella associated with its delayed release may be apparent. Watch the horse turning in small circles and moving backward, assessing flexibility of the neck and back, limb coordination and placement, and any quivering movement of the tail suggestive of shivering.

Flexion Tests

The interpretation of flexion and extension tests is controversial.^{3,4} The force applied, the duration of flexion, the way in which the joints are flexed, and the work history of the horse may all influence the response. Positive results of flexion tests in a horse that does not demonstrate lameness before flexion may not be a cause for termination of the examination, unless other suspicious clinical signs have been identified already. The horse should be evaluated on the lunge and ridden for evidence of lameness. Many positive results on flexion tests are found to change during the course of the exercise examination (perhaps as the horse warms up or loosens up), and these may not have clinical significance. A difference in response between distal limb flexion of the left and right forelimbs may be more important than a symmetrical response. A positive response to carpal flexion or to proximal limb flexion of a hindlimb must be viewed with caution. Veterinarians should aim to perform flexion tests as consistently as possible so that they know the ranges of response anticipated in clinically normal horses.

Lunging and Ridden Exercise

The requirements for lunging and ridden or driven exercise vary among the guidelines for prepurchase examinations in different countries and also are dictated by the type of horse under examination. The methods used for a 3-year-old Thoroughbred racehorse differ from those for a 6-year-old destined for eventing. Seeing the horse lunged on soft and hard surfaces and ridden is helpful to gain maximum information about any potential lameness problems. The vendor should be encouraged to use any protective boots or bandages that might be used normally. Subtle lameness or restriction in gait because of thoracolumbar or sacroiliac discomfort may not be evident until the horse performs specific movements when it is ridden.^{5,6} Small figure eights and upward and downward transitions may be particularly revealing. Watching the horse do what it specifically is intended to do is good practice. The veterinarian should watch the horse being tacked up and mounted to learn about any cold back behavior or evidence of back pain or other behavioral abnormalities. The horse should be worked reasonably hard relative to its fitness. In many European countries, evaluating a ridden horse is not standard practice, and if an examination is being performed on behalf of the client by a foreign veterinarian, the client should be advised accordingly.

Clinicians who have the prerequisite skill and experience may wish to evaluate horses further by riding or driving them themselves. Feeling the horse in this fashion may answer questions regarding a peculiar gait or way of going and may aid the evaluation of subtle lameness or respiratory noises. Such practice should be done with caution, because legal problems could arise from an unfortunate accident. A signed disclaimer may be helpful in this situation.

After strenuous exercise the horse should be allowed to stand for 15 to 20 minutes before being reevaluated in hand at the walk and the trot. This is a mandatory part of the examination in the United Kingdom but is not practiced widely in the rest of Europe. Previously inapparent lameness now may become evident. Any previously questionable response to flexion tests may be reassessed.

EVALUATION OF IDENTIFIED PROBLEMS

The veterinarian should now have gained enough information either to discontinue the examination after consultation with the purchaser or to make recommendations for further special examinations. If the horse is lame and a potential cause that may resolve is obvious (e.g., nail bind), reevaluating the horse on a subsequent occasion may be worthwhile, but the veterinarian should try to ensure that the horse has been worked properly for several days before the reexamination.

The veterinarian should always bear in mind that in a mature competition horse, it is relatively unusual not to identify some problems. Taking no risks and advising against purchasing the horse is easy, but that actually may be doing the purchaser, the vendor, and the veterinary profession a disservice. It is important to weigh the risks and describe them to the purchaser as objectively as possible, based on previous experience. At this point having in-depth knowledge of the purchaser, his or her aspirations for the horse, and the attitude to risk and financial ability to take the consequences of risk is most valuable. Further information obtained from radiographic and ultrasonographic examinations may help provide further objective information on which decisions can be based. Decisions also must be related to the horse's recent competition record, its age, and the future expectations for athletic performance. Low-grade hindlimb lameness associated with mild radiological changes of the distal hock joints might be an acceptable risk for a horse as a schoolmaster for a young rider, but similar abnormalities identified in a 6-year-old about to step up a level in competition must be regarded as potentially more serious. A veterinarian always must bear in mind that minor problems may become major problems with a change of rider, work pattern, and environment.

RECTAL EXAMINATION

Rectal examination is not a routine part of a prepurchase examination and should be performed only with the vendor's consent if indicated clinically or if a mare is to be used later for breeding or has a recent history of breeding.

RADIOGRAPHIC EXAMINATION

Radiographic examination is not a standard part of a prepurchase examination. The extent of routine radiographic examination in the United States and some European countries is probably higher than elsewhere. In Holland and Germany a strict grading system for evaluation of radiographs is used. The purchaser must be made aware that the presence of some radiological abnormalities is not necessarily synonymous with future lameness and the absence of radiological changes does not preclude future lameness.⁷ If radiographs are to be obtained for a specific area, then a comprehensive set of radiographs should be ordered to avoid missing lesions apparent on only one images. In many European countries, obtaining only three images in evaluation of the hocks and omitting a dorsomedial-plantarolateral oblique image are common. This practice may risk the veterinarian missing lesions such

Fig. 114-3 • Dorsomedial-plantarolateral oblique radiographic images of the left (**A**) and right (**B**) hocks of a 9-year-old Grand Prix show jumper. There is a small osteophyte on the proximal aspect of the third metatarsal bone (MtIII) (arrow), and subtle modeling of the articular margins of the centrodistal joint is present in each hock. The horse was clinically sound. **C** and **D**, The same horse 24 months later. At this stage the horse showed right hindlimb lameness that was alleviated by intraarticular analgesia of the tarsometatarsal joint. Considerable periarticular osteophyte formation (arrows in **D**) involves the centrodistal and tarsometatarsal joints of the right hock (**D**). The spur on the dorsoproximal aspect of the left MtIII was little changed (arrow).

as periarticular osteophytes, which are present only on the dorsolateral aspect of the joints (Figure 114-3).

The regions to be examined and the interpretation of findings are dictated by the previous and intended career of the horse and the results of the clinical examination. Examination of the front feet, fetlock, and hock joints is considered routine in many countries. Evaluation of the carpi, hind fetlock and pastern joints, stifles, and dorsal spinous processes of the thoracic region may be considered. It is, however, important not to overinterpret the clinical significance of some radiological abnormalities, bearing in mind the variability among breeds and the knowledge that even some obvious changes may be clinically insignificant. For example, Warmblood breeds have a tendency to have a greater number of radiolucent zones along the distal border of the navicular bone than do Thoroughbreds (Figure 114-4). A relatively high incidence of spur formation on the dorsoproximal aspect of the middle phalanx occurs in Warmbloods (Figure 114-5), but this rarely is associated with lameness. However, one of the authors (RDM) recognizes a higher incidence of clinically significant osteoarthritis (OA) of the proximal interphalangeal joint in Warmblood horses compared with other breeds.

Evidence of abnormal radiolucent zones in the proximal sesamoid bones (sesamoiditis) (Figure 114-6) should

alert the veterinarian to reevaluate the branches of the suspensory ligament. An ex-racehorse may have periosteal new bone on the dorsal aspect of one or more carpal bones, but this is unlikely to influence the horse's career as an event horse. A horse with a small osteochondral fragment on the dorsal aspect of the distal interphalangeal or metacarpophalangeal joint is often asymptomatic.

A small spur on the dorsoproximal aspect of the third metatarsal bone (MtIII) is a frequent incidental finding.⁸ However, such findings also must be described to the purchaser, and the potential future clinical significance must be discussed. Small spurs on the dorsoproximal aspect of the MtIII do not necessarily reflect OA but may reflect enthesioid new bone at the attachment of the fibularis (peroneus) tertius or cranialis tibialis. Despite the fact that these spurs are a common finding, accurately predicting the future behavior is impossible. Some spurs may reflect OA and may be progressive (see Figure 114-3). A 3-year-old that has done little work and has small osteochondral fragments at the cranial aspect of the intermediate ridge of the tibia may be asymptomatic, but if fragments became unstable with increased work, it might result in distention of the tarsocrural joint capsule, and surgical removal may be indicated. Such a finding in a mature competition horse is usually of no consequence. Complete fusion of the

Fig. 114-4 • A, Dorsoproximal-palmarodistal oblique image of the right front foot of a clinically normal 6-year-old Dutch Warmblood horse with good foot conformation. Note the large size and number of the radiolucent zones along the distal border of the navicular bone. The horse competed successfully for many years with no evidence of foot pain. **B,** Palmaroproximal-palmarodistal oblique image of the same foot. Note the large, oval-shaped lucent zones in the medulla of the navicular bone.

Fig. 114-5 • Lateromedial radiographic image of the left front pastern of a clinically normal 7-year-old Belgian Warmblood show jumper. Note the modeling of the dorsoproximal aspect of the middle phalanx (arrow). Such spurs are a common finding in Warmblood breeds and usually are not associated with lameness.

centrodistal (distal intertarsal) joint may be identified unassociated with any other radiological change of the hock (Figure 114-7). Some horses may compete successfully with such changes for many years, but occasionally lameness subsequently develops because of pain associated with the talocalcaneal-centroquartal (proximal intertarsal) or tarsometatarsal joints. Well-rounded osseous opacities

Fig. 114-6 • Dorsolateral-palmaromedial oblique image of a 6-year-old Thoroughbred that had raced previously on the flat and was used now for eventing. Note the large lucent zones in the lateral proximal sesamoid bone. The horse had no history of lameness.

Fig. 114-7 • Lateromedial radiographic image of the left hock of a 9-year-old clinically normal Thoroughbred advanced event horse. The centrodistal joint is fused completely. The horse competed successfully for another 8 years before being retired because of a tendon injury.

frequently are identified distal to a proximal sesamoid bone (Figure 114-8). These are often innocuous, but ultrasonographic evaluation of the distal sesamoidean ligaments may be indicated. Evidence of osteochondrosis of the trochleas of the femur is of concern in a 3-year-old, even if the horse is asymptomatic, whereas mild flattening of the lateral trochlear ridge of the femur in a 10-year-old jumper free from lameness would be of no concern.

NUCLEAR SCINTIGRAPHIC EXAMINATION

Nuclear scintigraphic examination is not a routine part of a prepurchase examination. If the horse is clinically normal, the interpretation of results of whole body screening is difficult. This practice should be discouraged. In selected horses when interpretation of the clinical significance of specific radiological abnormalities may be in dispute, focused nuclear scintigraphic examination may be helpful.

Fig. 114-8 • Lateromedial radiographic image of the left forelimb of a clinically normal 7-year-old Thoroughbred. There are two well-rounded osseous opacities distal to the proximal sesamoid bones. Such opacities are usually clinically innocuous.

ULTRASONOGRAPHIC EXAMINATION

Ultrasonographic examination of the limbs requires three important prerequisites: high-class image quality, experience of interpretation (knowledge of normal anatomy and its variations and the ability to detect abnormality and to interpret its potential clinical significance), and client compliance. A number of clinical situations occur in a prepurchase examination in which ultrasonographic examination provides invaluable clinical information not otherwise available. These situations include the following:

- An event horse that has competed in a Three Day Event within the last 6 months but has not competed since or a racehorse that has run recently but has not done fast work since. Strain of the SDFT, unilateral or bilateral, is a common injury in event horses and racehorses. Clinical signs of localized heat and swelling may resolve quickly or even pass unnoticed by the vendor (see Chapter 69). Clinical signs of tendonitis may be inapparent at the prepurchase examination but may become evident when fast work is resumed. If the left and right SDFTs are slightly enlarged with rounded margins but are symmetrical, this may pass unnoticed during the clinical evaluation.
- An event or racehorse that has not competed or raced in the last several months during the season. The purchaser may have given a plausible explanation for this, but the clinician should be suspicious that the absence from competition may reflect injury.
- Known previous tendon or ligament injury. Ultrasonographic examination gives more objective information than can be obtained from palpation alone but does not give information about strength of the structure.

- Suspected enlargement of one or more tendinous or ligamentous structures, detection of localized heat, or pain on palpation.
- Moderate enlargement of a digital flexor tendon sheath, especially if unilateral, particularly in a forelimb.
- Enlargement on the palmar (plantar) aspect of the pastern. It can be difficult to determine by palpation alone if thickening reflects localized fibrosis or swelling of a tendon or ligament.

Interpretation of findings in a horse with no identifiable clinical abnormality may not be straightforward, but enlargement of a tendon or ligament usually does reflect previous injury, the future relevance of which depends on the intended use of the horse, chronicity of the lesion, severity of the lesion, and degree of healing.

If ultrasonographic examination is recommended but is refused by the vendor or the purchaser, this should be noted on the prepurchase examination certificate.

THERMOGRAPHIC EXAMINATION

Thermography also may provide a useful indicator of low-grade inflammation and help to identify signs of early tendonitis, suspensory desmitis, and splint development. However, a normal thermographic appearance does not preclude the presence of a subclinical tendon lesion.

MAGNETIC RESONANCE IMAGING

The availability of MRI (especially the standing application) may lead to requests for more “thorough” examinations. MRI should be discouraged as a routine procedure because of the high probability of finding lesions in otherwise sound mature performance horses. It may be appropriate in situations where unusual radiological or ultrasonographic lesions are found, to further assess the possible clinical significance.

BLOOD TESTS

The use of blood tests is controversial, and limitations should be discussed with the prospective purchaser. Screening for nonsteroidal antiinflammatory drugs, mood-altering drugs, sedatives, and possibly also corticosteroids is advisable, but the purchaser must be aware that blood tests are less sensitive for these drugs and metabolites than is urine analysis. If the vendor knows in advance that the horse will be tested, this knowledge may provide a deterrent to the unscrupulous. Alternatively, blood may be collected and stored suitably and be analyzed only if a problem arises within the first few weeks of purchase. In the United Kingdom the Veterinary Defence Society and the Horse Race Forensic Laboratory run a scheme jointly. The vendor signs a form to permit collection of the sample in a specialized container provided by the Horse Race Forensic Laboratory, to which is applied a bar-coded label. The purchaser can elect to have the sample analyzed immediately for a fee or it can be stored at the Horse Race Forensic Laboratory at no charge with the potential for analysis at a later date. This system has proved to be legally robust.

The purchaser must be aware that drugs administered intraarticularly may not be detectable, depending on the

nature of the drug and the time of administration relative to the time of examination. In professional dealers' yards in Europe, a high incidence of joint medication to mask lameness occurs.

If the horse is being purchased in one country for export to another, testing for evidence of specific diseases may be necessary. For example, horses entering the United States should be tested for equine infectious anemia, dourine, glanders, and piroplasmiasis. A horse from an area where African horse sickness has occurred should be tested. Testing stallions going to the United States for equine viral arteritis is advised. Positive horses may not be permitted back into the European Union and other regions without extensive testing and potential limitations.

Screening for contagious equine metritis may be indicated. Use of hematological and serum biochemical screening and other assays, such as measurement of cortisol and insulin, as an aid to detect equine Cushing's syndrome in older horses is controversial. Routine hematology and serum biochemistry may be useful to ensure that the horse is healthy at the time of the examination. Serum testing for equine protozoal myelitis potentially is misleading and should be actively discouraged.

NERVE BLOCKS

In some circumstances, nerve blocks may aid interpretation of clinical findings. A horse may appear completely sound under all circumstances but have an unusually short forelimb stride. Does this reflect bilateral foot pain, or is this gait completely normal and natural for this horse? With the vendor's permission this question could be answered by bilateral perineural analgesia of the palmar nerves at the level of the proximal sesamoid bones. However, nerve blocks are not without complications and only establish the region of the pain causing lameness at best. Pursuing this course may prove frustrating and not elucidate the cause of the lameness.

If a horse is lame but the vendor claims that the horse has never been lame previously, the situation should be discussed with the purchaser. Reexamining the horse on a subsequent occasion may be best, but the vendor should be advised that after resolution of the lameness the horse must be worked for at least a week before reassessment. The veterinarian should ask the vendor to sign a form declaring that the horse has been worked properly and has not received medication, and the veterinarian should collect blood for medication testing when the horse is reexamined.

The examining veterinarian's role is not to perform a lameness investigation; this would be unethical. A lameness investigation is a job for the vendor's own veterinarian.

SUMMARY OF OBSERVATIONS

The veterinarian should summarize the basic assessment of the horse's physical condition for the buyer. Abnormalities of conformation, clinically insignificant swellings, and any clinical abnormality should be discussed and documented. The initial report should be made verbally to the client or the client's agent. When dealing with an agent,

informing the agent that the client also will be receiving a complete written report is wise. Comments should be as factual as possible, with minimal personal bias, but findings must be interpreted and the risk assessed and documented.

Although the veterinarian is working for the buyer, the veterinarian does have an obligation to the seller. The findings should not be discussed with anyone other than those involved in the sale. With permission of the buyer, the veterinarian can divulge any and all information to the seller.

A written report reviewing the findings of the examination should be provided to the buyer. The American Association of Equine Practitioners has an excellent set of guidelines for reporting the prepurchase examination (www.aaep.org/purchase_exams.htm). This report can serve as documentation of clinically significant findings for future reference.

The veterinarian should advise the buyer about the risks of purchase, without making the decision for the buyer. The veterinarian is not responsible for assessment of the suitability of the horse for a rider or for determining an appropriate value for the horse. However, if the horse is clearly likely to be unsuitable for the purchaser because of temperament or ease of management or riding, the purchaser should be advised accordingly.

GUIDELINES FOR REPORTING PREPURCHASE EXAMINATIONS

The American Association of Equine Practitioners has approved the following guidelines for reporting equine prepurchase examinations. The spirit of these guidelines is to provide a framework that aids the veterinarian in reporting a purchase examination and to define that the buyer is responsible for determining if the horse is suitable. These guidelines are neither designed for nor intended to cover any examinations other than prepurchase examinations (e.g., limited examinations at auction sales and other special purpose examinations such as lameness, endoscopic, ophthalmic, radiographic, and reproductive examinations). Although compliance with all of the following guidelines helps to ensure a properly reported prepurchase examination, the veterinarian has the sole responsibility for determining the extent and depth of each examination. The American Association of Equine Practitioners recognizes that for practical reasons not all examinations permit or require veterinarians to adhere to each of the following guidelines.

1. All reports should be included in the medical record.
2. The report should contain the following:
 - a. A description of the horse with sufficient specificity to identify it fully
 - b. The time, date, and place of the examination
3. The veterinarian should list abnormal or undesirable findings discovered during the examination and give his or her qualified opinions as to the functional effect of these findings.
4. The veterinarian should make no determination and express no opinion as to the suitability of the horse for the purpose intended. This issue is a business judgment that is solely the responsibility of the

buyer that he or she should make on the basis of a variety of factors, only one of which is the report provided by the veterinarian.

5. The veterinarian should record and retain in the medical record a description of all the procedures performed in connection with the examination, but the examination procedures need not be listed in detail in the report.
6. The veterinarian should qualify any finding and opinions expressed to the buyer with specific references to tests that were recommended but not performed on the horse (e.g., radiography, endoscopy, blood and drug tests, electrocardiography [ECG],

rectal examination, nerve blocks, laboratory studies) at the request of the person for whom the examination was performed.

7. The veterinarian should record and retain the name and address of parties involved with the examination (e.g., buyer, seller, agent, witness).
8. A copy of the report and copies of all documents relevant to the examination should be retained by the veterinarian for a period of years not less than the statute of limitations applicable for the state in which the service was rendered. Local legal counsel can provide advice as to the appropriate period of retention.

Chapter 115

Lameness in the Show Hunter and Show Jumper

*Robert P. Boswell, Richard D. Mitchell,
Timothy R. Ober, Philippe H. Benoit,
Christopher (Kit) B. Miller, and Sue J. Dyson*

HISTORICAL PERSPECTIVE

Show jumping and related competitions have origins in hunting sport and military tradition. The show hunter, most popular in North America, has evolved from the traditions of fox and stag hunting. These horses were expected to provide fast, safe, and athletic passage for the rider, and considerable pride was taken in being well mounted and having the horse admired. Today in the show ring these horses are judged for beauty, athletic ability, manners, and way of going. Jumping style is important and must be coupled with consistent performance.

Some competitions encourage the development of a young horse to a higher level of training, others award a mature horse for outstanding performance, and others separate amateur and professional riders. Horses often are selected based on suitability for a particular division of competition.

The modern show jumper has many of its origins with military traditions. Many cavalry officers were by necessity highly skilled and accomplished horsemen. Thus when the era of the modern Olympics began, the equestrian competitors were military men. With the mechanization of the military and the replacement of the cavalry with motorized transport, the private sector became more involved in Olympic show jumping. Many of the early civilian competitors were retired military men. Show jumping has become increasingly more popular, and many talented riders have emerged on the national and international scenes. Since the 1960s many women have entered this sport, once dominated by men.

STRUCTURE OF THE SPORT

Show jumping combines athletic effort of the horse and rider. The scoring process is objective, with the winner jumping the course with the fewest rails knocked down and, in the jump off, in the fastest time. Heights of fences range from 1 m at novice level to 1.7 m for advanced competitions. The course should be completed within an allowed time, and some competitions are considered as speed classes in which jumping and time faults are combined. As the jumps get bigger, the potential for injury increases, and many conditions develop from repetitive strain. Many of the fences are set at distances to each other so that the horse must adjust stride length to fit in the appropriate number of strides. A good horse must have explosive power and great athleticism, combined with carefulness—a desire not to hit fences. Contrary to many equine sports, similar numbers of mares and geldings or stallions compete (Figure 115-1).

Fig. 115-1 • A Grand Prix show jumper jumping a large oxer at Spruce Meadows, Calgary, Canada, a venue with one of the most lucrative prize structures worldwide. Note the symmetrical position of each of the forelimbs and hindlimbs. Asymmetry may reflect an underlying pain-related problem. The horse is jumping squarely across the fence; jumping obliquely may reflect hindlimb pain and uneven propulsion.

Some older horses compete at levels of competition lower than they have reached to be schoolmasters for less experienced riders. These older horses may experience unique problems related to age and use. Today show jumping is a highly diverse and competitive sport enjoyed all over the world from beginner level to the level of the Olympic Games. At the top level the sport is entirely professional, with horses changing hands for huge prices and with large amounts of prize money available, putting pressure on the veterinarian to keep horses sound. Competition continues throughout the year, with outdoor shows during the summer months and indoor shows during the winter, so horses potentially get few breaks.

CHARACTERISTICS OF THE JUMPING SPORTS HORSE

Many breeds are capable of show jumping and related activities and include Thoroughbreds (TBs), European Warmbloods, TB-Warmblood crosses, and American Quarter Horses and related crosses. The European Warmbloods most often are represented by the Hanoverian, Holsteiner, Trakehner, Dutch Warmblood, Selle Français, Swedish Warmblood, and Irish crossbred breeds. Breeding in continental Europe has become highly specialized and has developed in part through financial support from state governments. Most modern day top-level show jumpers are naturally well-balanced, good-moving athletes. Various pony breeds, such as the Welsh crosses, are used for children (see Chapter 126).

Current preferences are for lighter and taller horses, with moderate muscling. This body type is associated with greater speed and agility, which are assets to a modern show jumper. This body type also benefits hunters because these horses have graceful movement, with good extension and natural balance. Larger horses, if not excessively heavy, are at an advantage for show jumping because of greater stride length and overall strength and power. The TB long has been preferred by American trainers for the hunter ring; however, in recent years Warmblood breeds have gained favor because of a calmer nature and better manners.

Horses often start competing at 4 years of age, reach peak ability at 9 to 12 years of age, and may continue to compete until 18 to 20 years of age.

TRAINING

Training of the hunter and jumper emphasizes using the hindquarters for engagement and collection, which places more weight and stress on the hindlimbs as they are brought forward and under the rider during locomotion. Such a posture is somewhat unnatural for the horse, whose normal inclination is to distribute weight over the forehand. These stresses may contribute to or accelerate the development of problems of the thoracolumbar and pelvic regions, and ligaments and joints of the hindlimbs. Early in the training of a young horse, lameness often reflects musculotendinous problems and relates to lack of adaptation to work.

When training over fences begins, new loads on the hindlimbs occur that place more stress on soft tissues and joints. Stresses on the forelimbs also are increased because they are involved in takeoff and landing. The forelimbs are

involved in setting up the jump and aiding in the directional change from horizontal to vertical. On landing the forelimbs receive considerable impact loads and absorb the entire weight of the horse. Increased load places more stress on the foot, distal limb joints, and the soft tissues of the forelimbs.

Horses must learn to adjust stride length by shortening or lengthening the stride, to jump from a line perpendicular to a fence or at an angle, to turn quickly, to change leading legs in canter, and to jump from variable speeds of approach. Unwillingness to change leads or always favoring one lead when landing after a fence may indicate a problem (see Chapter 97). Much of the basic flat work training is similar to dressage.

Many lameness conditions encountered early in a horse's training begin as subtle performance-limiting problems, progress relatively slowly, and may disappear with further conditioning. However, excessive training leads to the development of important problems such as chronic muscle soreness, fatigue, joint inflammation, and behavioral changes. Slow, steady work with a gradual buildup in exercise intensity and duration results in fewer joint and soft tissue problems later.

TRAINING AND COMPETITION SURFACES

Training, warm-up, and competition surfaces play a substantial role in the development of lameness in a jumper. Soft, deep footing requires much more effort by the horse and is responsible for early fatigue of muscles, tendons, and ligaments. Injuries include gluteal muscle strain and spasm, suspensory desmitis, desmitis of the accessory ligament of the deep digital flexor tendon (ALDDFT), and superficial digital flexor (SDF) tendonitis as well as inflammation of or trauma to any of the soft tissue structures in the hoof, pastern, and metacarpal and metatarsal regions. Sandy soils contribute to the development of hoof wall problems. Hard surfaces may result in bone- and joint-related injuries, as well as distal limb and foot problems such as subsolar bruising, distal interphalangeal (DIP) joint synovitis, and osteoarthritis (OA) of the proximal interphalangeal (PIP) and DIP joints.

Formerly most high level outdoor competitions in Europe took place on grass, but there is an increasing trend for some of the higher-level competitions to take place on all-weather surfaces. The nature of the footing depends highly on the weather and can vary extremely. To enhance traction, screw-in studs often are used in the front and hind shoes. Studs may be used in the medial and lateral branches of the shoe or just the lateral branch to reduce risk of interference injuries. If studs are used in only one branch of the shoe, this immediately creates mediolateral imbalance and the potential for abnormal torque. Studs also alter the dorsopalmar balance, especially if the ground is firm. Horses that flex the carpi excessively during jumping may have to wear a girth guard to protect the sternal region from self-inflicted injuries. If a horse is jumping on firm going, studs concentrate the forces of impact and can predispose the horse to deep-seated bruising of the foot. There is a tendency in horses with poor-quality horn for the hoof wall to break in the region where studs are placed. In some circumstances studs may halt the normal slide of a foot on landing and thereby predispose to injury.

Excessive work, such as long period of lunging a hunter to calm it down, prolonged competitive efforts, and long show schedules of repeated competitions play a role in the development of many injuries in hunters and jumpers.

CONFORMATION AND LAMENESS

Conformational abnormalities of the foot predispose horses to lameness. An underrun heel, long toe, and a broken hoof-pastern axis frequently contribute to palmar foot pain and DIP joint synovitis. Horses with improper medial-to-lateral hoof balance may develop a sheared heel, crushed bar, and chronic foot pain. Base-wide or base-narrow forelimb conformation may contribute to injuries to the suspensory ligament (SL), its branches, and the distal sesamoidean ligaments.

Toe-in or toe-out forelimb conformation may predispose horses to PIP and metacarpophalangeal joint problems. Short, more upright pasterns predispose horses to navicular disease and DIP joint and PIP joint synovitis or OA. These horses are often straight through the shoulder as well and lack the stride and extension necessary for jumping. Long, more sloping pasterns sometimes are associated with sesamoiditis and soft tissue injuries to the distal aspect of the limb.

Over-at-the-knee conformation may predispose horses to SL strain and should be avoided in selecting a jumper. Offset-knee conformation predisposes a jumper to medial splint problems. However, attention always should be paid to subclinical contralateral hindlimb lameness in a mature horse that develops an acutely painful medial splint bone. Subtle angular limb deformities are rarely a problem, provided proper attention is paid to shoeing and hoof balance.

Extremely sickle-hocked conformation is associated with weak hindlimbs and places more stress on the plantar tarsal soft tissues and the centrodistal and tarsometatarsal joints. A straighter hock is actually more desirable, but an overly straight hock may predispose to SL strain and distal hock joint pain, especially in association with an extended fetlock and long pastern conformation.

Horses that are extremely straight through the stifle are poor jumping prospects and have a high incidence of instability and upward fixation of the patella. A more angular stifle gives the horse a longer, more powerful stride and is thought to provide more strength for jumping.

A long, sloping hip and croup are desirable characteristics in a jumping horse, providing strength and power. Horses with a flat croup often suffer from thoracolumbar and sacroiliac pain. Asymmetry of the tubera sacrale and tubera coxae can be seen in the absence of lameness and may reflect previous trauma. An experienced rider usually can manage these horses.

Horses with excessively base-wide or base-narrow hindlimb conformation place abnormal stress on the feet and joints. Base-wide horses may have an increased incidence of hock problems, whereas base-narrow horses may have more stifle problems.

SHOEING CONSIDERATIONS

Many lameness problems are a direct result of improper trimming and shoeing. Neglected feet are frequently a source of lameness, and a poorly shod foot also may

contribute to lameness by forcing the horse to transfer abnormal and excessive stresses to other parts of the limb or to other limbs. Many of the Warmblood breeds have relatively tall, narrow upright feet, which are predisposed to the development of thrush and sheared heels. Others have wide flat feet that can be carelessly shod into a broken back hoof-pastern axis with an underrun heel and abnormal orientation of the distal phalanx. Studs in the shoes may create foot imbalance and may increase the severity of interference injuries. A good cooperative relationship with an experienced farrier is an essential element in lameness prevention and management. This can be a problem for top-level competition horses that are constantly moving from show to show and are being trimmed and reshod by different people with varying ability. The time of shoeing relative to the day of competition is important because trimming may alter biomechanical forces. To avoid increased stresses on the soft tissue structures within the hoof capsule, it is suggested that the horse be shod within a maximum of 4 weeks from competition. In Europe we consider 7 to 15 days to be the optimum interval between shoeing and competition (PHB, SJD).

LAMENESS EXAMINATION

Before a horse is examined because of a suspected lameness problem, several factors should be considered. If the horse is currently competing, will any diagnostic tests or treatment have an effect on the horse's ability to continue competition? Knowledge of the competition rules and drug use guidelines are essential. Has the horse recently competed? Has a change in exercise intensity or duration been made? Does the horse have a new trainer? When was the horse last shod? If the horse has been competing away from home, it is important to determine if another veterinary surgeon already has examined and treated the horse, and if so with what.

The lameness examination should begin as the horse is walked from the stall or paddock to the examination room or area, because movements such as a small circle to reverse its direction may offer clues as to which limb or limbs may be affected. It is not uncommon for there to be concurrent lameness in more than one limb. Careful observation and palpation of the joints of each limb as well as the neck and back are performed while the horse is held quietly. Passive flexion tests and evaluation of the lateral movements of the head, neck, and back are performed.

A dynamic examination should be performed beginning with an observation of the horse at the walk in a straight line, in small circles, and in a figure eight. The horse should next be examined at the trot in hand on a firm, level surface. Lunging on firm footing in small circles in both directions should be performed, as this often exacerbates subtle lameness, especially if involving the foot.

It is sometimes necessary to see the horse ridden to determine which limb is lame. The rider may also be asked to change the diagonal at the trot and figure eight to increase the load on a specific limb when it is on either the inside or the outside of the circle.

Examinations performed after strenuous exercise or after competition may be useful; more subtle lameness may then be more obvious. It should also be noted and recommended that the veterinarian observe the "way" or

“style” the horse trains and jumps. Defects in the horse’s position and way of jumping that would have otherwise gone unnoticed may be observed during a routine physical or lameness examination. Watching videos of the horse may also allow the practitioner to see abnormalities of the horse’s balance or gaits when in motion. Knowing what is “normal” may also help the practitioner detect early or subtle changes in movement before an obvious lameness is manifest.

Proximal and distal limb flexion tests should be performed on all limbs. The method and duration of flexion are a matter of personal preference but should be consistent and interpreted with care, bearing in mind that joints and soft tissue structures may be stressed simultaneously. It has become common practice for top-level competition horses to be examined periodically throughout the year to try to detect early warning signs of impending problems. A positive response to flexion is often followed by treating the stressed joint(s). The true value of this practice is difficult to determine objectively.

Once the lame limb(s) has been identified, the limb is carefully reexamined. Hoof tester response should also be assessed. An obvious source of pain may be identified, but perineural or intraarticular analgesia often is required to localize the source(s) of pain. Results are sometimes confusing and always should be related to the clinical examination.

Aseptic preparation is essential for intrasynovial injections to minimize the risk of infection. Two authors (RPB, CBM) also administer gentamicin intravenously before entering any synovial space. The conditions of the work area and the temperament of the horse being examined influence which analgesic technique to use. Intrasynovial analgesia may be delayed or not performed if no clean, dry place is available for safe injection. Although intraarticular analgesia is considered to be more specific than perineural analgesia, it may influence periarticular pain. In some instances regional or intraarticular analgesia may not be safely performed without first tranquilizing the horse. This may interfere with the lameness examination, especially if the lameness is low grade. Lameness is reassessed after the effects of sedation have worn off. Alternatively the horse is sedated, the suspected joint is treated with the appropriate drug(s), and the horse is reevaluated in a few days. The treatment is therefore substituted for intraarticular analgesia. In situations in which subtle lameness makes interpretation of nerve blocks difficult, in those horses with multiple-limb lameness, in horses that are difficult or dangerous, or when comprehensive blocking fails to localize the lameness, other techniques such as nuclear scintigraphy should be considered.

When horses are competing regularly, especially away from home, owners, riders, trainers, and peers often put pressure on the veterinarian to treat the horse based on an index of clinical suspicion rather than on a complete lameness evaluation including local analgesia. Although this can be successful and a positive response to treatment clearly indicates a correct diagnosis, one must bear in mind that some injuries do require rest for the best long-term outcome. A merely transient response to treatment or a lack of response warrants further investigation of the lameness, and this routinely should include local analgesic techniques.

IMAGING CONSIDERATIONS

Only after successfully localizing the source of pain causing lameness or after an extensive physical examination has provided the veterinarian with a reasonable indication of the problem should the examination progress to diagnostic imaging, including radiography, ultrasonography, and, if indicated, nuclear scintigraphy, computed tomography, or magnetic resonance imaging (MRI). Routine techniques are used, with no special images. High-quality diagnostic imaging is related directly to the veterinarian’s success as a diagnostician. The routine use of both ultrasonography and radiography is strongly encouraged, as soft tissue structures are commonly involved in injuries of the bone and joints. The complete extent of the injury may be identified; the presence of a soft tissue component may influence both the treatment options and the prognosis. Frequent ultrasonographic examinations make a practitioner more confident in correctly recognizing an abnormality.

FAILURE TO MAKE A DIAGNOSIS

Every veterinarian, no matter how astute as a lameness diagnostician, eventually will be confused or unsure or simply have no idea as to why a particular horse is lame, and consultation with associates or referral to other experts should be considered. Just as a good relationship with a farrier is paramount to the successful management of many foot-related problems, good relationships with other veterinarians are necessary and may be helpful when one is faced with a difficult or confusing lameness. The veterinarian must be honest and open about the horse with the owners and trainers; inclusion of other professionals in the case or referral for advanced imaging may ultimately lead to both an accurate diagnosis and enhancement of the veterinarian’s relationship with the client if handled well. Reexamination at a later date also may be beneficial. Some bone lesions may take a few weeks to become visible radiologically, so the veterinarian should consider reimaging if the pain causing lameness has been localized to a specific area.

The use of many medications for a “shotgun” approach to treatment may be a veterinarian’s only hope when all diagnostic methods are either unrewarding or not available and if previously attempted “trial therapies” have failed. Such medications include but are not limited to nonsteroidal antiinflammatory drugs (NSAIDs), doxycycline, tiludronate, intramuscular polysulfated glycosaminoglycans (PSGAGs), intravenous hyaluronan, and oral nutraceuticals.

TREATMENT

In recent years the trend has been toward much more aggressive treatment, with many different treatment modalities often being combined to manage a single condition. Although in some circumstances this can be justified, it does mean that the veterinarian is often not sure which treatment really is effective. More targeted treatment based on a precise diagnosis actually may be equally effective. A thorough understanding of the overall “pain map” of the horse can lead to a confident approach to treatments even in the absence of objective data from the lameness

examination. The pain map essentially represents the postulated sites of pain causing poor performance based on an assessment of a detailed history of performance; the results of palpation including the response to stimulation of acupuncture points; evaluation of the horse moving in hand, on the lunge, and ridden, both when work is first initiated and later in the work program; and the response to flexion tests and chiropractic assessment of joint mobility, sometimes combined with assessment of the response to local analgesic techniques (TRO).

TEN MOST COMMON LAMENESS PROBLEMS OF SHOW HUNTERS AND SHOW JUMPERS

1. Foot pain
2. Distal hock joint pain
3. Suspensory desmitis
4. Thoracolumbar region pain
5. Fetlock region pain
6. Stifle pain
7. Osteoarthritis or trauma of the proximal interphalangeal joint
8. Croup and hip region pain
9. Superficial digital flexor tendonitis and desmitis of the accessory ligament of the deep digital flexor tendon
10. Cervical osteoarthritis and pain

Many of these problems are interrelated, and more than one problem may occur simultaneously. We have attempted to list these in relative order of frequency; however, this is not intended to imply that one is more serious than another.

DIAGNOSIS AND MANAGEMENT OF COMMON CAUSES OF LAMENESS

Foot Pain

Foot Soreness

The most common site of forelimb lameness and overall lameness in a hunter or jumper is the foot. The horse naturally supports 60% to 65% of its body weight over the forelimbs, and impact forces during jumping dramatically increase load and structural stresses in tissues within the hoof capsule. This may be exacerbated by training regimens that do not focus on improving strength from behind and therefore the overall balance of the horse.

The manner in which a horse is shod has tremendous importance in the development of hoof- and foot-related problems. A long toe and underrun heel are common hoof conformational defects and frequently contribute to heel pain because of hoof wall separation or bruising in the heel, quarter, and bar areas. The heel itself may be excessively long and collapsed inward, and the horse actually may be bearing weight on the outer wall. This often results in sensitivity to hoof tester pressure applied to each heel bulb and when the heel bulbs are squeezed together. A flattened and chronically bruised heel and bar area (corns) may be seen after removal of the shoe.

Lameness is often improved by analgesia of the palmar digital nerves. Lateromedial radiographic images of the foot may reveal that the distal phalanx is abnormally oriented, in extreme situations so that the palmar aspect of the bone is lower (more distal) than the toe (so-called

“negative palmar angle”). The so-called “negative palmar angle” appears to occur more commonly in the United States than in Europe. The solar margins of the distal phalanges may be irregular. In horses with chronic lameness, deep digital flexor (DDF) tendonitis and distal sesamoid impar desmitis may contribute to pain associated with an underrun heel. However, these soft tissue injuries have been documented using MRI in show jumpers with both poor and good foot conformation (SJD).

Some horses with underrun heels and poor angulation of the distal phalanges do not respond well to shoeing. Removing the shoes, trimming back the abnormal heel wall, and placing the foot in a support bandage are recommended. One author's (RPB) preference is to fashion a cushion support for the palmar aspect of the hoof using a two-part putty elastomer material (EDSS, Equine Distal Support System, Penrose, Colorado, United States). Using the sulci of the frog for support is believed to suspend the heel and promote the new growth to be more vertical in its orientation. This process, however, requires a long-term commitment by the owner and trainer, because new heel growth may take up to 6 months to be sufficient for the reapplication of shoes. One author floats the heel using a $\frac{3}{4}$ rim pad and either a heart bar shoe or a pour-in pad in an effort to keep the horses in work and competition (CBM).

Attention should be paid to the role of training and overall management of the horse, specifically as it relates to hindlimb strength and comfort.

Subsolar Bruising

Horses with subsolar bruising often respond well initially to Epsom salt poultices or cooked linseed hoof packs and NSAIDs (e.g., phenylbutazone) followed by corrective shoeing. Rasping excessive toe from the solar surface proximally up the dorsal wall to create a 45-degree angle with the ground surface and application of a shoe fitted full at the heel may be of benefit by removing resistance to breakover. Ideal breakover is located between two points; the first is located by extending a line distally along the dorsal surface of the distal phalanx to the bearing surface, and the other by drawing a perpendicular line from the dorsal distal aspect of the distal phalanx to the bearing surface. Egg bar shoes may be required to gain adequate heel support. Shoes such as the EDSS natural balance shoe (Equine Digital Support System), with the web behind and squared off at the toe, also improve breakover and reduce stress in the palmar portion of the foot. We do not recommend the long-term application of plastic wedge pads or egg bar shoes because they actually may contribute to further crushing of the heel and promote the heel bulbs to slide forward and grow horizontally. Leather pads may be helpful in some horses if sole pain is present and sole protection is desired. In horses with a chronic problem, long-term use of aspirin (60 g once daily or 20 g bid for 5 days) may be helpful. Hoof growth supplements containing biotin and methionine also may be of benefit, and we recommend feeding of biotin (100 mg to 1 g for 3 to 12 months, either alone or combined with zinc, cysteine, and DL-methionine daily) to promote hoof wall growth. Careful attention should be paid to the condition of the gastric mucosa with long-term NSAID use in show horses, because gastric ulceration may occur or worsen. Concurrent

administration of acid pump inhibitors such as omeprazole should be considered.

Extreme sensitivity to hoof testers may be evident along the periphery of the sole at the level of the distal phalanx. Such pain may be associated with bruising, solar margin fractures, laminar inflammation or inflammation of the distal phalanx caused by chronic concussion from hard ground, or excessive sole pressure from the shoe. These conditions may be more common in North America (with its harder and dryer footing) than in Europe. Radiology is necessary for diagnosis of solar margin fractures of the distal phalanx. Shoeing should be directed at reducing local pressure on the affected areas and improving the overall hoof balance. Egg bar shoes and rim pads are often effective, but soft sole pours that provide extra cushion and shock absorption also help. Two-part putty elastomer is thought to benefit by providing support and lift from the sulci of the frog. Care should be taken with a pour or putty elastomer to avoid overfilling, causing excessive sole pressure.

Subsolar Abscess

Subsolar abscesses occur commonly and result from shoe nails improperly applied, poor environmental conditions, a shoe moving slightly, and poor hoof structure. Onset of clinical signs may be rapid, such as immediately after a show, or may occur within the first several days after shoeing. The additional trauma of jumping exacerbates the condition, leading the rider or trainer to suspect trauma or serious injury. Warmth in the hoof wall, increased digital pulse amplitudes, and focal, extreme sensitivity to hoof tester application are usually diagnostic, provided that the hoof horn is not excessively hard. Perineural analgesia is rarely necessary to confirm the suspected diagnosis and also may be confusing, because not all horses respond positively. After blocking and trotting the horse to reassess lameness, reexamination of the solar surface of the foot may reveal purulent drainage from the area of suspicion. Treatment is directed toward liberal opening of the solar surface of the foot at the point of maximum sensitivity to establish adequate drainage. If drainage is not established, bandaging the foot with hyperosmotic agents such as products containing magnesium sulfate (Epsom salts) is recommended. Twice daily soaking of the foot with a hot, supersaturated solution of Epsom salts with the bandage left on is also recommended for 3 to 5 days. Once drainage has been established, the foot is bandaged in a similar fashion, and NSAIDs also may be administered to reduce the inflammation. Antibiotics rarely are indicated but are sometimes used if soft tissue swelling occurs above the coronary band.

Navicular Disease

Navicular disease may initially be misdiagnosed as inflammation of the DIP joint. It is also likely that navicular disease is overdiagnosed in horses with simple heel pain. The diagnosis of navicular disease carries the stigma of a permanent and disabling lameness and is upsetting to the horse owner and trainer. Therefore the veterinarian should make an exhaustive effort to rule out all other possible sources for the pain causing lameness before making the diagnosis.

Lameness in horses with navicular disease usually is characterized by a slow, insidious onset. Early signs include

shortening of the stride length, tripping, toe stabbing, and an intermittent unilateral lameness, although the lameness is almost always bilateral. Show horses are often more lame the day after a competition. Some horses with no previous lameness history become suddenly lame and are often refractory to standard therapies. Recent experience using MRI suggests that a proportion of horses that were previously thought to have navicular disease have primary lesions of the deep digital flexor tendon (DDFT) within the hoof capsule (SJD). Some horses with navicular disease also have an acute-onset unilateral lameness. The response to hoof testers varies, and often the horse shows only resentment when the heel bulbs are squeezed together. The wedge test may accentuate lameness; however, a positive response is not pathognomonic for the disease. Lameness may be increased after distal limb flexion, but the response is nonspecific. Lameness is almost always eliminated by palmar digital nerve blocks, and a previously undetected lameness often appears in the contralateral limb. Analgesia of the DIP joint or the navicular bursa often improves or abolishes the lameness.

Interpretation of the radiological appearance of the navicular bone is not easy; many horses with navicular bone pain have no detectable radiological abnormality. Radiolucent cystlike lesions in the body of the bone, large lollypop-shaped radiolucent areas on the distal border of the bone, increased thickness of the flexor cortex, and enthesophyte formation on the proximal and distal borders of the bone should be considered clinically significant.

Nuclear scintigraphy may be useful in horses that appear normal radiologically. The solar image is most useful and may reveal increased radiopharmaceutical uptake (IRU) in the navicular bone, reflecting abnormal bone metabolism. Lateral pool phase images may also be useful for highlighting horses that may have DDF tendonitis within the hoof capsule.

Ultrasonographic examination of the navicular bone and its associated soft tissue structures through the window of the frog may be useful, especially if MRI is not an option. It potentially allows assessment of the palmar aspect of the navicular bone, and the DDFT and the distal sesamoidian impar ligament and the insertions on the distal phalanx. MRI is useful for the diagnosis of various forms of navicular disease, identifying bone abnormalities not visible radiologically (Figure 115-2) and associated soft tissue injuries.

Therapy for navicular disease includes pain management and corrective shoeing. Clients should be advised that this disease rarely is cured and requires a long-term commitment to its management. Horses with chronic, refractory lameness may require neurectomy.

Trimming and shoeing should be directed toward facilitating breakover, providing support to the palmar aspect of the foot, and in some horses elevating the heel to reduce tension in the DDFT. A full fitted egg bar shoe with a rockered toe or the EDSS natural balance shoe may be useful. The forward edge of the shoe should be set back from the toe and the branches fitted full at the heel. Leather wedge pads have been used to elevate the heel; however, the foot should be monitored closely to prevent crushing of the heel. A commercially available aluminum wedge-shaped shoe also may be used to provide heel elevation. It should also be noted that horses with palmar foot pain associated

Fig. 115-2 • Transverse T1-weighted gradient echo magnetic resonance image of a foot. Medial is to the left. There is increased signal intensity in the flexor cortex of the navicular bone medial to the sagittal ridge (*arrow*), dorsal to which signal intensity in the spongiosa is also increased, bounded dorsally by a rim of reduced signal intensity. There is dorsal irregularity of the deep digital flexor tendon in the same sagittal plane as the navicular bone defect (*arrowhead*).

with injury to the DDFT often demonstrate improvement in lameness when shoes are removed.

Medical management includes the use of NSAIDs, isosuprine, pentoxifylline, tiludronate, and aspirin; intraarticular injection of the DIP joint and intrathecal injection of the navicular bursa with corticosteroids and hyaluronan; and rest. Many of these therapies, usually in combination, have proved successful in short-term management of this condition, and we generally would recommend the least-invasive therapies first. The degenerative nature of this disease, however, ultimately usually results in the failure of any treatment, and palmar digital neurectomy may be considered. Surgical case selection is important, and consideration should be given to the overall condition of the horse and its level of performance. This procedure is not allowed for horses competing under Fédération Equestre Internationale (FEI) rules. Horses with evidence of DDF tendonitis and PIP or DIP joint OA are not considered good candidates because of the possibility of rupture of the DDFT or exacerbation of OA. Some horses may experience temporary pain relief from the application of a chemical nerve block using a mixture of corticosteroids, ammonium sulfate, and Sarapin locally injected at the level of the palmar digital nerves. This procedure may work well initially, only to gradually lose its effectiveness.

Shock wave therapy recently has been introduced as a noninvasive therapeutic option for pain management in horses with navicular disease. Several investigators have reported good results, but differences in equipment and protocols require further investigation. Positive results may be short-lived.

Sheared Heel

Sheared heel can be a serious problem in hunters and jumpers. Lameness is often insidious in onset, or a critical point of instability may be reached, producing a more acute lameness. Subtle conformational abnormalities and

poor hoof balance likely contribute to this condition. The medial heel bulb often is displaced proximally, with the remainder of the foot splayed laterally. When viewed from the solar surface of the foot, the lateral half of the foot is larger and flared compared with the medial half. The medial heel bulb may be painful to hoof testers, and the heel bulbs may be manipulated independently. Analgesia of the medial palmar digital nerve frequently improves lameness, but usually it is necessary to desensitize both heel bulbs before the horse appears sound. Many horses demonstrate radiological abnormalities of the medial palmar process of the distal phalanx, such as roughening or demineralization of the margin of the bone, presumably because of chronic trauma and inflammation. The therapeutic goal is to stabilize the heel bulbs and reduce pressure on the driven up or proximally displaced bulb. Stabilization most often is accomplished best by improving balance and breakover so that the foot lands flatly and relieving the affected heel from excessive loading during weight bearing. In a jumper an egg bar shoe with or without a pour-in pad to stabilize the heel is usually satisfactory. Horses with more severely affected feet may benefit from a heart bar, diagonal bar, or G-bar shoe. A rim pad with the portion to lie beneath the affected heel cut away may float the heel enough to allow that side to descend into a more normal position. Six to 9 months of persistent treatment are required before a more stable heel structure is established.

Distal Interphalangeal Joint Synovitis and Osteoarthritis

Inflammation of the DIP joint is common in jumping horses and usually results in subtle lameness that is frequently bilateral. Palpable joint effusion may or may not be present. Many horses, but not all, respond positively to a distal limb flexion test. Forelimbs are most commonly affected, but the hindlimbs also may be involved. The horse may have a reduction in stride length, and lameness is most obvious when the horse circles on firm footing. The rider or trainer may complain of a reduction in jumping performance, such as a reluctance to leave the ground and landing in a heap. Very hard surfaces for training or competition and surfaces that are too soft, irregular, and unstable may be predisposing factors. Soft footing, although not seemingly likely to contribute to excessive concussion, produces torsional forces on the DIP joint that strain the periarticular soft tissues. An underrun heel, long-toe conformation is probably the single most important contributing factor. The horse often shows a painful response to hoof testers with pressure applied from either heel to the opposite side of the frog and from the center of the frog to the dorsal hoof wall. Lameness usually is improved with analgesia of the palmar digital nerves and eliminated with palmar (abaxial sesamoid) nerve blocks or intraarticular analgesia of the DIP joint.

Radiological changes may be absent or subtle; however, in horses with more chronic or severe disease, active periosteal bone may be present on the dorsal aspect of the middle phalanx, and modeling of the extensor process of the distal phalanx may occur. With chronic, severe OA of the DIP joint there may be subchondral radiolucent areas in the distal phalanx consistent with collapse of the joint. Prominent radiolucent areas representing synovial invaginations may be present on the distal border of the

Fig. 115-3 • Parasagittal fat suppressed short tau inversion recovery (STIR) magnetic resonance image of the phalanges. There is a well-demarcated region of increased signal intensity on the distal dorsal aspect of the middle phalanx (arrow), reflecting bone trauma. This was associated with reduced signal intensity in T1-weighted images.

navicular bone. Ultrasonographic examination of the collateral ligaments should be performed.

Nuclear scintigraphy is useful to rule out bone involvement. An area of IRU in the synovial structures of the joint may be visible in pool phase studies. Differentiating the palmar pouch of the DIP joint from the navicular bursa is difficult, and both structures may be involved in horses with severe lameness.

MRI has proven extremely useful in identifying abnormalities in and around the DIP joint including osseous trauma of the distal aspect of the middle phalanx (Figure 115-3). However, osseous trauma of the middle phalanx can occur alone, without DIP joint pain.

Therapy for horses with DIP joint synovitis depends on the severity of the lameness and the horse's competition schedule. Proper trimming and shoeing as for palmar foot pain with attention to the medial-to-lateral hoof balance is essential. The use of NSAIDs is common. Peripheral vasodilating agents such as isoxsuprine are of questionable value, although higher-than-standard doses appear to be clinically effective.

Intraarticular injection of high-molecular-weight hyaluronan and corticosteroids (triamcinolone acetonide or betamethasone) with proper shoeing and an appropriate amount of rest usually yields the best results. Occasionally, repeated injections are necessary after 4 to 6 weeks; however, injections repeated more frequently than once every 3 months should be avoided and should prompt a thorough review of the shoeing and hoof balance. Nutra-ceuticals and parenterally administered chondroprotective agents (PSGAGs) may be beneficial. Interleukin-1 receptor antagonist protein (IRAP) is helpful in managing recurrent inflammation in the DIP joint. A series of three or four injections given 7 to 10 days apart often is effective at relieving lameness associated with chronic synovitis.

Other primary sources of pain causing forelimb overload should be investigated.

Collateral Ligament Injury of the Distal Interphalangeal Joint

Some horses with synovitis of the DIP joint that are unresponsive to therapy should be evaluated for possible

collateral ligament injury of the DIP and other anatomically related injuries. In a few horses, we (RDM, SJD) have identified enlargement and disruption of the infrastructure of the collateral ligament ultrasonographically, sometimes with focal IRU at the site of insertion on the distal phalanx, occasionally extending into the ipsilateral palmar process (SJD, RPB). MRI must be considered the gold standard for imaging structures in this area. Horses with collateral ligament injury should be managed with corrective shoeing and rest. Work level is reduced substantially. Extracorporeal shock wave or therapeutic ultrasound therapy combined with prolonged rest (at least 6 to 9 months) may be effective. Palmar digital neurectomy has been an effective management tool in horses failing to respond to conservative management (SJD).

Distal Hock Joint Pain

Distal hock joint pain is the second most common reason for lameness in a hunter or jumper and is the most common hindlimb lameness. Conformational defects, developmental abnormalities, and the incredible torsional stresses placed on the distal hock joints during jumping are thought to contribute to lameness. A variety of subtle signs becomes manifest before the onset of clinical lameness. Often the trainer or rider complains of a loss in the horse's stride length, poor impulsion, and a change in the horse's jumping style. Many horses may develop a tendency to switch leads in front of a jump or may have difficulty jumping from a particular lead. The horse consistently may develop the tendency to jump to one corner of the obstacle, and wider jumps appear to require more effort than usual or even necessary.

Clinical examination often reveals sensitivity to palpation of the muscles of the lumbar area and shortened cranial phase of the stride. The upper limb flexion test may reveal resentment of flexion and may or may not have a positive result. Some horses are reluctant to move forward immediately into a trot after flexion and may canter away from the veterinarian. Other horses may demonstrate an overall loss of balance after proximal limb flexion, manifesting as an induced forelimb lameness (TRO). The Churchill test often has a positive result in horses with tarsometatarsal (TMT) joint pain, but the result may be negative with centrodistal (CD) joint pain. Some horses with proximal suspensory desmitis (PSD) also respond positively to both proximal limb flexion and the Churchill test (RPB, RDM). Tarsocrural effusion may or may not be present. We (RPB, RDM) rarely perform regional perineural analgesia of the fibular and tibial nerves, because we consider the procedure difficult to interpret and somewhat dangerous to perform. Intraarticular analgesia of the CD and the TMT joints is preferred. However, a negative response to intraarticular analgesia does not preclude CD and TMT joint pain, and using fibular and tibial nerve blocks to identify some horses with distal hock joint pain may be essential. With practice this is a highly reliable and safe technique (SJD). With subtle hindlimb lameness or complaints of poor performance and no apparent lameness, it may be necessary for the horse to be ridden and for the rider to interpret the results of the block. The veterinarian should allow this with only the most experienced and talented riders.

Radiological changes vary from none to severe, with what may appear as total radiological evidence of joint

fusion. Radiological changes do not necessarily correlate to the degree of lameness, but extensive radiolucent regions are often associated with moderate lameness. Osteochondral fragments on the cranial aspect of the intermediate ridge of the tibia, or at the distal aspect of the medial trochlea of the talus in a mature athlete in the absence of lameness, are usually an incidental finding of little if any clinical significance. However, fragments on the cranial aspect of the intermediate ridge of the tibia are occasionally associated with OA of the tarsocrural joint. The severity of the degenerative changes may be similar in the CD and the TMT joints; however, the TMT joint often has less severe abnormalities. The reason for this is unclear.

Nuclear scintigraphy can be helpful and reveals IRU in the distal aspect of the tarsus. Occasionally, small, focal, moderate-to-intense areas of IRU may reflect focal areas of loss of joint space, bone trauma, or tearing of interosseous ligamentous attachments.

It has been generally accepted that radiological evidence of distal joint(s) fusion is desirable, because the suggestion is that once joint fusion has occurred, the inflammation and therefore the pain should disappear. This is an unfortunate myth. Surgical arthrodesis is a currently accepted treatment for horses with OA of the CD or TMT joints that have become refractory to routine therapies. We challenge this belief and have observed evidence to the contrary. Once arthrodesis has occurred, the normal function of the joint is lost. The distal joints are responsible for the dissipation of the twisting or torsional forces and shear stress in that area. With this capability gone, these forces are concentrated, and stress fracture of the central or the third tarsal bones may occur or OA of the talocalcaneal-centroquartal (proximal intertarsal) joint may develop (RPB, SJD).

Treatment of horses with distal hock joint pain varies. Intraarticular injections of corticosteroids (20 to 40 mg methylprednisolone acetate, up to 10 mg triamcinolone acetonide, or 5 to 7.5 mg betamethasone in each joint) and hyaluronan (2 mL per joint) is usually the first treatment, combined with NSAIDs, and is usually the best and most expeditious means of treatment. With radiological evidence of severe OA we use a long-acting corticosteroid alone. Treating horses with more mildly affected joints with a low corticosteroid dose in combination with hyaluronan may be chondroprotective and extend the useful life span of the joint. Combined therapies have grown popular because of the perception that they work better and the effects last longer. Most horses respond favorably, and the riders comment on how much better the horse performs. Many horses, especially those with demanding show schedules, have the hocks (and perhaps other joints also) routinely injected at intervals predetermined by the history of when the horse previously became unsound after previous injections. Maintenance treatment is performed about 1 month earlier. This reduces the risks of loss of performance, recurrent lameness, or development of a secondary problem. However, we strongly advocate that horses should undergo periodic clinical reappraisal to determine the current cause or causes of suboptimal performance or lameness. Recurrent apparent hock pain should lead to investigation of other causes of lameness such as caudal back pain and PSD.

Many horses also are treated with oral nutraceuticals, parenterally administered PSGAGs, and intravenously administered hyaluronan. These products are incorporated into a maintenance program designed to keep the horse comfortable and prolong the interval between intraarticular joint injections. Frequently the large size of these horses means that they are treated with twice the normal dose of PSGAGs. Horses often are treated with intramuscularly administered PSGAGs and intravenously administered hyaluronan the evening before competition. Occasionally, horses with joints unresponsive to corticosteroids and hyaluronan do respond to intraarticularly administered PSGAGs, with or without corticosteroids. Once the horse has been made more comfortable, an exercise program consistent in intensity and duration, emphasizing strengthening the hindquarters and abdominal muscles, improves performance. Shock wave therapy has been effective in controlling the pain associated with severe OA of the distal tarsal joints. In addition, intravenous tiludronate has proven beneficial in some horses. Shoeing is aimed at encouraging breakover in the center of the hoof by squaring the toe. Alternative therapies such as muscle massage and acupuncture are used commonly with traditional therapies.

Suspensory Desmitis

Injury to the SL is the most common soft tissue injury and certainly one of the most serious injuries of jumping horses. Early lesions may go unnoticed by even the most skilled horseman, because the rider or trainer is aware of only a vague problem that the horse warms out of fairly quickly. With bilateral hindlimb injury the rider may complain of loss of power. Exercise continues, and the injury eventually worsens to the point of causing enough damage to produce obvious lameness. With forelimb injury the lameness usually is more pronounced when the horse is trotted in a circle with the affected limb on the outside and also may be exacerbated in soft footing. With hindlimb injury lameness may be worse with the lame(r) limb on either the inside or the outside of a circle. Midbody and branch lesions are diagnosed easily by palpation; however, diagnosis of PSD is more challenging. The distal limb flexion test may be resented and substantially increase the lameness in horses with midbody and branch lesions, whereas carpal flexion and upper hindlimb flexion frequently accentuate lameness associated with PSD, which can cause confusion with hock pain. Perhaps injuries to the distal aspect of the branches and at the insertion onto the proximal sesamoid bones (PSBs) may lead to fetlock joint instability. Careful examination of the distal aspect of the ipsilateral splint bone should be performed in horses with chronic desmitis of the branches or distal aspect of the body. A high palmar metacarpal nerve block, direct infiltration of the SL origin, or analgesia of the lateral palmar nerve eliminates lameness in the forelimb. Analgesia of the proximal aspect of the hindlimb SL requires caution, because injury to both the veterinarian and the horse can occur. Analgesia is best performed with the horse restrained with a twitch and the leg positioned in the veterinarian's lap as if the horse's foot were being examined. Displacing the digital flexor tendons medially and isolating the SL for injection is thus easier. The SL is infiltrated with local anesthetic solution from the axial aspect of the lateral

splint bone, fanning across the SL from lateral to medial. During injection, the local anesthetic solution should go in with considerable resistance if it is being deposited within the SL itself. Another technique involves having an assistant hold the limb in a similar fashion and making an injection medially 1.5 cm distal to the chestnut along the axial margin of the DDFT in a dorsolateral direction. Depositing 3 to 6 mL of local anesthetic solution within the SL can then be accomplished, usually with little objection by the horse. Alternatively, perineural analgesia of the deep branch of the lateral plantar nerve can easily and safely be performed with the limb bearing weight (SJD). With direct infiltration of the ligament, soundness should be almost immediate. Some risk exists of entering the distal palmar outpouchings of the carpometacarpal joint capsule using direct infiltration in the forelimb, causing potential diagnostic confusion; however, infiltration in the hindlimb inadvertently entering the tarsometatarsal joint is less likely. With hindlimb injury there may be associated pain in the sacroiliac joint region.

Ultrasonographic examination of the SL may reveal obvious lesions; however, finding minimal evidence of damage in horses with acute injuries is not uncommon. Recent nerve blocks may confuse interpretation, so ultrasonographic examination is best delayed for 1 to 2 days. Alternatively, ultrasonographic examination may precede nerve blocks. In our opinion, ultrasonographic imaging of the proximal SL in the hindlimb is difficult. The transducer should be placed on the plantaromedial aspect of the limb to get the best-quality images. A cross-sectional area of greater than 1.5 cm² suggests PSD, even in the absence of a focal or diffuse loss of echogenicity. Comparison with the contralateral hindlimb is essential.

Radiographic examination of the proximal aspect of the third metacarpal bone (McIII) or third metatarsal bone (MtIII) may demonstrate increased radiopacity with or without radiolucent defects in a dorsopalmar (dorsoplantar) image or subcortical increased radiopacity in lateromedial images. Incidental radiological changes can be seen in hindlimbs, especially in older horses.

Nuclear scintigraphy has proved useful in characterization and prognosis of some horses with PSD. The pool phase occasionally reveals pooling of radiopharmaceutical in the ligament. A characteristic pattern of IRU is present in the forelimbs and hindlimbs in the bone phase. The lateral image is most important in the forelimb because focal IRU is present on the proximopalmar aspect of the McIII if bone injury accompanies PSD. PSD occurs often without chronic changes in the palmar or plantar cortex of the McIII or the MtIII. Dorsal images of the forelimb are less sensitive than lateral images because the limb is farther away from the gamma camera. In hindlimbs lateral and plantar images have similar sensitivity. The veterinarian should not mistake for a lesion IRU in the proximolateral aspect of the metatarsal region in plantar images, which is a normal finding. Ultrasonographic abnormalities of the SL and abnormal scintigraphic images confirm injury to the bone at the origin of the SL, indicating a complex injury involving two tissue types and adversely affecting the prognosis. IRU in the proximal aspect of the McIII or the MtIII in the absence of detectable ultrasonographic abnormalities may reflect primary osseous injury, which can be confirmed using MRI. MRI has also been useful in the diagnosis of PSD

when the condition is not evident ultrasonographically and for identification of concurrent osseous pathology.

Medical therapy for horses with suspensory desmitis varies. NSAIDs combined with rest and physical therapy have historically been considered the only option, and clients were advised that treatment could take 6 to 12 months. We recommend stall rest for 10 to 14 days after the injury, with twice daily handwalks in an effort to cool the ligament down. Recently, new therapies (adult bone marrow-derived stem cells, growth factors, platelet-rich plasma [PRP], pigs' urinary bladder matrix [A-Cell]) have become available and show early promise; however, long-term follow-up on a large number of horses is required. After the injection the limb is kept bandaged for at least 2 weeks. Phenylbutazone is administered (2 g bid for 4 days and then 1 g bid for 10 days) after the injection. Walking under saddle then is commenced for 20 to 30 minutes once or twice daily for the next 30 days. Follow-up ultrasonographic examinations are performed after 30 days and every 30 to 60 days thereafter. The duration and intensity of exercise gradually are increased based on the ultrasonographic appearance of the SL and the clinical appearance of the horse. Trotting begins once the horse is sound. Some veterinarians in North America recommend an internal blister, using 2% iodine in almond oil infiltrated into the SL. Light exercise is continued immediately after this therapy, with a gradual return to full work. Shoeing should be improved if necessary. In horses with acute PSD with no substantial ultrasonographic changes, local injection of corticosteroids may decrease inflammation and eliminate pain. We use triamcinolone acetonide (12 to 18 mg), betamethasone (30 mg), or isoflupredone acetate. Sarapin (4 mL) also may be added. If there is IRU in the McIII or the MtIII, there is anecdotal evidence that tiludronate may be effective.

Recently a surgical procedure has been reported in which the tight fascia overlying the proximal aspect of a hindlimb SL is transected in order to reduce pressure or in this apparent compartment syndrome. Bone marrow aspirate collected from the sternum then is injected into the area of the injury in an effort to stimulate healing. Early results from this technique appear promising; however, further investigation and long-term follow-up information are needed. Neurectomy of the deep branch of the lateral plantar nerve together with fasciotomy have been used successfully for management of horses with hindlimb PSD, with approximately 70% of horses returning to long-term full athletic function (SJD). Osteostixis of the proximal plantar aspect of the MtIII may also help with some horses with chronic injuries with radiological abnormalities but is invasive and has yet to be shown effective in a large number of horses.

Shock wave therapy has been used successfully to treat suspensory desmitis of the origin, body, and branches, especially in horses with bone involvement at the origin. This technique provides profound analgesia and therefore may decrease or even eliminate the lameness.

Horses with larger lesions within the body of the SL or its branches may benefit from splitting alone. This appears to allow a more complete healing of core lesions, which otherwise may be slow to resolve.

Therapeutic ultrasound or infrared laser therapy may aid and reportedly speed healing, although evidence is mainly anecdotal.

Shoeing should be directed at supporting the toe and preventing it from sinking deeper into the ground surface than the heel on weight bearing. If this happens, the heel is elevated, the fetlock drops, and strain is applied to the suspensory apparatus. A shoe with a wide toe is commercially available and helps to prevent the toe from sinking.

Selection of the footing during the convalescent period and when work is resumed is vital, together with careful modification of the training program.

Back Pain

Back pain is common in jumpers, and although signs are recognized easily, the etiological diagnosis may be elusive and complex. The trainer or owner may perceive that a horse has back pain from many clinical signs including sensitivity to grooming and saddling, resistance to rider weight, overall body stiffness, poor performance, and pain on palpation of the muscles over the back. Careful examination of the horse under saddle and over fences and a good working relationship with professional riders can be of great help in interpreting and localizing the type of back pain. Many clinical signs are also common to other diseases or injuries and may be secondary to clinical or subclinical hindlimb lameness resulting in or from an altered gait. Primary back pain may be caused by muscle strain, impingement or overriding of the spinous processes, diskospondylosis, sacroiliac desmitis, supraspinous desmitis, OA of the synovial intervertebral articulations (facet joints), and sacroiliac joint pain.

The veterinarian should first attempt to rule out any lameness. Horses with distal hock joint, stifle, or gluteal muscle pain may swing the hindlimb outward away from the body or inward toward the midline in an attempt to reduce the degree of joint flexion required to advance the limb. Hindlimb lameness should be suspected in horses with simultaneous gluteal and back pain. Horses with bilateral hindlimb PSD may hold the back stiffly and mimic a horse with primary back pain. Chronic forelimb soreness, particularly involving the foot, also may contribute to cervical and/or thoracic pain because of an inverted way of jumping that somewhat protects the foot on landing. Teeth problems or neck pain also should be considered.

Severe back pain suggests a primary back problem. The horse may move with a shortened, stiff gait and appear to be flat or hollowed out in the back when ridden but appear much more comfortable when moving free in a paddock or on the lunge. Injection of local anesthetic solution into the painful areas of the back may change the horse's movement.

Impinging Spinous Processes

Radiology of the thoracolumbar spinous processes may reveal impingement with increased radiopacity, bone proliferation, and radiolucent defects. Nuclear scintigraphy can be used to diagnose and support the diagnosis of spinous process impingement and osteitis, although false-negative results are sometimes obtained. Occasionally, areas of IRU are visible in the spinous processes without any radiological changes, and supraspinous ligament desmitis should be considered.

The treatment for impingement of the spinous processes or supraspinous desmitis is similar. NSAIDs and methocarbamol are prescribed routinely for a prolonged

period. Sarapin and corticosteroids frequently are injected between and around the impinging spinous processes. The locations for injection are determined best by placing a radiodense marker on the top of the back during radiography and then identifying the affected vertebrae by clipping the hair. Mesotherapy may be useful: small doses of flumethasone, lignocaine, Traumeel (a homeopathic remedy), and normal saline are delivered intradermally with 0.4- to 0.6-cm 27-gauge needles on a multiport injection rack. Numerous rows of skin blebs are formed after the injections, and pain relief is almost immediate. Shock wave therapy is also helpful.

Muscle Injury and Pain

Acute muscle strain may be accompanied by spasm, which is evident as a firm, painful swelling. Palpation of the psoas and lumbar muscles can also be performed transrectally, and pressure may also be applied to the caudal and ventral sciatic nerve roots as well. Immediate application of ice and administration of NSAIDs such as phenylbutazone or naproxen are beneficial. One author (RPB) also administers 20 to 40 mg of dexamethasone once daily for 2 days in horses with acute pain. Later, moist heat and therapeutic ultrasound reduce pain and inflammation. Local treatment with mesotherapy is useful when treating back muscle pain. Acupuncture has proved useful in managing horses with back pain no matter what the cause. Chiropractic manipulation may be of some benefit in relieving pain and muscle spasm. Pulsating magnetic field therapy is used routinely in show jumpers for the long-term management of back pain. Shock wave therapy has also been used successfully to treat and manage jumpers with back muscle pain.

Saddle fit always should be evaluated critically in a horse with chronic or recurrent back pain, and thermography may be helpful, together with advice available through most good saddle manufacturers.

Fracture of the Withers

Fracture of the withers is not uncommon if a horse flips over backward. The withers area may appear flat and is extremely painful to palpation. The horse plaits in front and holds the neck stiffly. Radiographs are diagnostic. Treatment is directed toward reducing pain and inflammation by applying ice and administering NSAIDs immediately after the injury. Bone sequestrae occasionally develop, and purulent drainage may appear weeks after the injury. However, most fractures are uncomplicated, and horses usually may be able to return to work after 6 to 12 months.

Sacroiliac Joint Pain

Sacroiliac strain is common in show jumpers. Many horses have chronic low-grade pain that never seems adversely to affect the ability to perform. With severe pain a horse may stand parked out (the hindlimbs are extended unusually) and rest one hindlimb. Unilateral lameness may develop, and the horse's performance then is affected severely. The horse may experience pain on palpation around the lumbosacral region and directly over the tubera sacrale, but this is not specific. Exerting pressure on one of the tubera sacrale may reveal slight motion and even may be resented by the horse. The horse may offer considerable resistance when one of the hind feet is picked up and the limb is

flexed high. Rocking the pelvis may cause the horse to grunt. Injection of local anesthetic solution deep into the muscles directed toward the sacroiliac articulations should be performed with caution because the horse may lose its ability to stand. Transrectal ultrasonographic examination may reveal irregular margins of the caudal aspect of the sacroiliac joint and may be useful to support a clinical diagnosis. Evaluation of the ventral sacral nerve roots and the lumbosacral joints may be useful. Nuclear scintigraphy may reveal little if any IRU in this region and is therefore unreliable, but with modern motion-correction software and improved image quality, useful information is acquired in some horses (SJD).

Rest and time are the most important factors influencing the outcome. Horses lame from acute sacroiliac strain may require at least 6 months to heal. Severely affected horses should be given stall rest for 30 days, followed by 2 to 3 months of controlled paddock rest. Light exercise then may begin, gradually increasing the intensity and duration of the work. In our experience, acupuncture has been extremely useful for pain management and the treatment of muscle spasm.

Horses with less severe injuries may be managed successfully by local injections of corticosteroids and Sarapin deep into the painful areas. These horses are able to continue to exercise and compete successfully. The procedure involves directing a 15- to 25-cm needle from a point just medial to one of the tubera sacrale along the inner surface of the ilium deep toward the sacroiliac articulation or using ultrasound guidance and approaching the sacroiliac joint from a cranial dorsal ipsilateral aspect and a caudal dorsal route to treat both sides of the horse. One author (RPB) prefers to use all three approaches on each side. A combination of corticosteroids and Sarapin is injected; however, some practitioners have reported good results with IRAP and bone marrow aspirate as well. Deep injections from either side of midline to the transverse processes of the caudal lumbar vertebrae also help. For 2 weeks after treatment, the rider is cautioned not to collect the horse or perform aggressive lateral movements. Proper and careful rehabilitation is paramount to avoiding recurrence of the problem. Horses with sacroiliac disease are more predisposed to injury when competing at indoor shows, performing high jumps with tight turns.

Injection of the acupuncture points on either side of or parallel to the sacrum with the same solution also may be performed. Chiropractic manipulation often is attempted in horses with sacroiliac injury. Although chiropractic has proved useful as a diagnostic tool and may be of benefit with mild sacroiliac strain, manipulation of the sacrum in horses with more severe injuries never replaces the need for prolonged rest. Pulsating magnetic field therapy, cold laser, and therapeutic ultrasound may be used for the long-term management of chronic sacroiliac problems.

Osteoarthritis of the Thoracolumbar Synovial Intervertebral (Facet) Joints

OA of the synovial intervertebral (facet) joints may be contributing to thoracolumbar region pain, and diagnosis is by radiography and ultrasonography. Ultrasound-guided periarticular injections through the fascia of the multifidus muscle may be of benefit. Careful and progressive warm-up exercises are important.

Fetlock Joint

Synovitis and Osteoarthritis

Metacarpophalangeal or metatarsophalangeal joint synovitis and OA are common in older horses with lengthy careers. Chronic capsulitis results in a thickened, prominent joint capsule with a dramatic decrease in the flexibility of the joint. At least a moderate amount of joint effusion occurs, but many sound horses may have chronic effusion, thickening of the joint capsule, and reduced range of motion. The source of pain is confirmed by a low four-point palmar or plantar nerve block or intraarticular analgesia.

Radiological examination may reveal osteophyte formation on the proximal aspects of the proximal phalanx and the PSBs and flattening of the sagittal ridge of the McIII or the MtIII. The McIII or the MtIII may have a scalloped appearance on the dorsal or palmar/plantar aspect in horses with advanced OA. Subchondral radiolucent areas may develop in the McIII or the MtIII or the proximal phalanx and may result from severe, focal trauma or end-stage OA. The prognosis for horses to return to athletic competition after the development of these lesions is considered poor. Acute fractures and small chips are uncommon in hunters and show jumpers. Small, round, smooth fragments on the proximodorsal aspect of the proximal phalanx are seen in forelimbs and hindlimbs. These fragments represent osteochondrosis and are rarely associated with lameness but occasionally may become unstable and require removal.

Nuclear scintigraphy may reveal mild-to-moderate IRU in the distal, dorsal aspect of the McIII or the MtIII, the proximodorsal aspect of the proximal phalanx, or both. In some horses flexed lateral images are required to separate the bones, especially if IRU in one area is so intense that identifying the adjacent structures is impossible.

In the absence of substantial radiological abnormalities, medical therapy should include NSAIDs, intraarticularly administered corticosteroids and hyaluronan, and orally and parenterally administered PSGAGs. Horses with chronic OA or those difficult to manage may benefit from regular treatment with IRAP. Physical therapies such as icing, cool water therapy, poultices, sweats, cold laser, therapeutic ultrasound, support wraps, and rest are also beneficial. Arthroscopic exploration of the metacarpophalangeal joint is indicated if the response to medical treatment is transient or poor. Clients should be advised that although the causal problem may be revealed, treatment may not be possible. Debridement of damaged cartilage and subsequent replacement with fibrocartilage may be curative; however, excessive erosion of the articular cartilage warrants a poor prognosis for continued jumping.

Therapeutic shoeing targeted at providing support to the palmar aspect of the foot, such as a wide-web shoe, may be of benefit (RDM, RPB). One author prefers an aluminum shoe with short branches, which decreases extension of the fetlock, especially when the horse is landing (PHB). Proper medial-to-lateral hoof balance is also important in reducing torque on the metacarpophalangeal joint.

Sesamoiditis

Sesamoiditis frequently is associated with chronic suspensory branch desmitis. Horses are variably lame and may

warm out of the lameness. The distal limb flexion test usually is resented and results in increased lameness. The suspensory branches may be palpably thickened and painful. Intraarticular analgesia of the metacarpophalangeal or metatarsophalangeal joint may improve lameness but does not alleviate it. Lameness is abolished by a low four-point palmar/plantar nerve block.

Abnormal radiological findings include linear lucent zones or lytic areas within the body of the PSB. A generalized loss of bone opacity or proliferative, reactive bone also may be present on the abaxial margins in association with suspensory branch desmitis and insertional lesions of the SL and palmar/plantar annular ligament. We find proximodistal oblique images of the PSBs useful.

Nuclear scintigraphy is sensitive to inflammation in the PSBs, and IRU in the PSBs often is intense. A flexed lateral image helps to separate the PSBs from the McIII or the MtIII. Dorsal or plantar images are required to distinguish between the medial and lateral PSBs.

Treatment for horses with sesamoiditis includes rest, NSAIDs, and supportive shoeing similar to that prescribed for fetlock joint problems. Shock wave therapy may be helpful.

Stifle Joint Pain

Problems involving the stifle joint are common in show jumpers and frequently accompany problems in the tarsus. Joint effusion is present variably. Stifle pain may be primary and related to trauma, mechanical problems, developmental diseases, and OA, or it may be secondary to other lameness. Primary problems include OA, osteochondrosis, meniscal and cruciate ligament trauma, upward fixation or delayed release of the patella, and patellar desmitis. Signs may be subtle at first, with mild shortening of the stride or switching leads at the canter or gallop. Caudal back pain also may be present. The proximal or upper limb flexion test may or may not have a positive result, and the veterinarian should look closely for subtle gait changes such as a shortening of the cranial phase of the stride. Separation of stifle and tarsal pain may be accomplished by flexing the stifle with the hock slightly extended so that the metatarsal region is held behind the tail and perpendicular to the ground, with the tibia held parallel to the ground. The Churchill test also may help to separate hock from stifle pain. Cranial to caudal motion of the tibia relative to the femur during weight bearing (cruciate test) may produce a change in stride; however, it is not routinely performed and has been replaced by abducting and adducting the limb in an attempt to stress the stifle (RDM). However, intraarticular analgesia always is required to confirm the source of pain.

Horses with straight stifle conformation are predisposed to upward fixation and instability of the patella. Pain results from subsequent patellar ligament strain and synovitis. Although the limb may be observed to lock in extension, more frequently a slight hesitation in the advancement of the limb is noted. Femoropatellar effusion may be present.

Ultrasonographic examination of the patellar ligaments may reveal desmitis characterized by enlargement and a focal or diffuse hypoechogenic region. Horses with transient upward fixation of the patella benefit from NSAIDs and an increased exercise program designed to increase muscle tone in the quadriceps group, which stabilizes the

patella. Failure to respond to these measures may justify a more aggressive procedure, such as local injection of 2% iodine in almond oil at the proximal aspect, middle portion, and insertions of all three patellar ligaments and into the muscle just proximal to the stifle. This procedure has proved effective in treating transient upward fixation of the patella and subtle soreness in the adjacent muscles. A "splitting" (desmoplasty) of the medial patellar ligament may be performed in horses with more severe upward fixation of the patella. This induces desmitis of the ligament and subsequent thickening. Anecdotal reports describe benefit from estrone sulfate, estradiol, and calcium channel blockers. Jumpers with primary patellar ligament injuries require rest.

Cranial Cruciate Ligament and Meniscal Injury

Trauma to the cranial cruciate ligament produces profound lameness. Intraarticular analgesia of the femorotibial joints may or may not abolish the lameness, and radiographs of the stifle may be normal in horses with an acute injury. With chronic injury new bone may be seen cranial to the intercondylar eminences, most obvious in a flexed lateromedial image. Injury to the medial meniscus is most common. Intraarticular analgesia of the femorotibial joint on the affected side usually produces improvement in the lameness. Radiographs may reveal osteophyte formation on the proximomedial aspect of the tibial plateau indicative of OA and a subjective decrease in the joint space width on the affected side.

Ultrasonographic examination of the stifle is routinely performed and enables assessment of parts of the medial and lateral menisci, the cranial meniscal ligaments, the articular surfaces of the medial and lateral condyles and trochlear ridges, the medial and lateral collateral ligaments, the patellar ligaments, and the tendons originating from the femur and tibia. The presence of joint effusion can also be assessed. Evaluation of the cranial cruciate ligament is challenging.

Osteochondrosis and Subchondral Bone Cysts

Osteochondrosis and subchondral bone cysts should be considered in a young Warmblood that has recently started training or increased its training intensity and has developed lameness localized to the stifle. Intraarticular analgesia usually at least partially eliminates the lameness. We recommend blocking all three joint spaces.

Radiographs are usually diagnostic. Arthroscopy may be indicated. Horses with subchondral bone cysts and other lesions in the medial femoral condyle usually have a poorer prognosis than those with osteochondrosis of the lateral trochlear ridge of the femur. We recommend radiography of the stifles as part of the routine radiographic study when a young Warmblood is examined for purchase.

Nuclear scintigraphy of the stifle in horses with osteochondrosis may reveal little if any IRU. Both caudal and lateral images should be obtained. IRU (to any degree) in the medial femoral condyle in a caudal image almost always is associated with a pathological condition (RPB).

Synovitis and Osteoarthritis

Mature horses may develop synovitis and OA of any one or a combination of the stifle joints. Often the femoropatellar and medial femorotibial joints are involved; however,

lateral femorotibial OA may occur alone. Intraarticular analgesia of all three joints should be performed.

The diagnosis may or may not be confirmed radiologically. Osteophyte formation on the proximal medial aspect of the tibia is not uncommon. Nuclear scintigraphy may reveal mild-to-moderate IRU in the femoral condyle and the opposing surface of the tibia on the affected side in a caudal image. Ultrasonographic examination often reveals mild soft tissue inflammation and may be more sensitive than radiography for identification of periarticular osteophytes.

Intraarticular injection of corticosteroids and hyaluronan usually has favorable results. Each joint should be injected separately with double doses of a high-molecular-weight hyaluronan combined with methylprednisolone acetate (40 to 80 mg) or betamethasone (5 to 10 mg). In many horses treatment of the medial femorotibial joint alone is successful (RDM, SJD). NSAIDs, parenterally administered PSGAGs, and intravenously administered hyaluronan are also beneficial and may be used routinely with nutraceuticals as part of a maintenance program. Adequate rest also should be prescribed; however, strict stall confinement is usually not appropriate. Walking these horses under saddle for 30 minutes once or twice daily is preferred. Alternative therapies such as those described for distal tarsitis are also beneficial. Acupuncture commonly is used for managing horses with stifle pain. Recurrent synovitis of a stifle that has been injected repeatedly is suggestive of a more serious injury such as meniscal damage causing some degree of joint instability; therefore, prolonged rest or exploratory arthroscopy should be considered.

Pastern

The pastern region is subject to considerable stress in the jumping horse. OA of the PIP joint is not uncommon and often is associated with OA of the DIP joint. Horses with base-narrow or toe-in conformational defects are affected most frequently. Distal sesamoidean desmitis is also a common problem. Trainers complain that many horses with OA of the PIP joint start out stiff when training and feel much better after warming up, but eventually the lameness becomes persistent. With chronic injury comes obvious thickening in the distal aspect of the pastern. Palmar (abaxial sesamoid) nerve blocks normally eliminate the lameness, although a low palmar (four-point) block sometimes is required. Intraarticular analgesia of the PIP joint also usually produces soundness. The veterinarian must beware that a palmar digital nerve block may alleviate lameness associated with OA of the PIP joint because of proximal diffusion of the local anesthetic solution and the distal palmar extension of the joint capsule.

There is usually greater RU in the subchondral bone of the PIP joints of sound jumping horses relative to other joints. With OA the intensity of the IRU usually increases. We (RPB, RDM) therefore believe that subclinical OA of the PIP joint is common. Radiological changes in horses with OA of the PIP joint include osteophyte formation on the proximodorsal aspect of the middle phalanx. Subchondral osseous cystlike lesions in the proximal aspect of the middle phalanx may be associated with severe trauma or end-stage OA. Acquired osseous cystlike lesions usually are associated with focal, intense IRU.

Management of horses with OA of the PIP joint includes using NSAIDs, intraarticularly administered corticosteroids and hyaluronan, and orally and parenterally administered PSGAGs. The horse should be trimmed and shod to reduce resistance to breakover at the toe and to balance the foot to land as flatly as possible. Occasionally, wedge pads provide comfort by opening up the dorsal aspect of the joint space. Shock wave therapy has been of benefit to horses with advanced ringbone and may be combined with intraarticular injection. Horses with severe OA of the PIP joint may respond poorly to medical management, and arthrodesis may be required. Arthrodesis is often successful in the hindlimbs of jumping horses, but results are often unsatisfactory in forelimbs. Tibial neurectomy also has been used successfully.

Soft Tissue Injury

Injury to the distal sesamoidean ligaments may or may not be accompanied by obvious swelling or pain on palpation. The oblique sesamoidean ligaments are most commonly affected, but jumpers with this injury have a better prognosis than those with injuries to the straight sesamoidean ligament. Analgesia of the palmar (abaxial sesamoid) nerves usually eliminates the lameness. Ultrasonographic examination reveals focal or diffuse hypoechogenic regions in the affected ligament. Palmar or plantar displacement of the DDFT medially or laterally may be secondary to distal sesamoidean ligament injury. The veterinarian should image all structures carefully in the pastern, because several structures may be injured simultaneously. DDFT injuries are more common in the pastern than in the metacarpal region (Figure 115-4). Chronic strain at the insertion of the oblique sesamoidean ligaments may be evident radiologically as enthesophyte formation on the palmar or plantar lateral and medial borders of the proximal phalanx.

Horses with strains and tears of the distal sesamoidean ligaments usually respond to supportive shoeing, NSAIDs, and rest. Horses with acutely torn ligaments may benefit from cast or splint application for about 1 month. Physical therapy such as therapeutic ultrasound may speed recovery. Shock wave therapy is routinely used to treat horses with injuries to the soft tissue structures in the palmar or plantar aspect of the pastern. Regenerative therapies such as those previously mentioned for the treatment of suspensory desmitis may also be of benefit. Injury to these ligaments usually requires 6 to 12 months for convalescence. Returning the horse to work too soon results in thickening and fibrosis of the pastern and prolonged lameness.

Croup and Hip Region Pain

Strain and inflammation of the gluteal muscles are common in jumping horses and sometimes result from an altered gait secondary to lameness elsewhere in the ipsilateral or contralateral hindlimb. Primary strain may occur in a horse during jumping, when a horse refuses a jump, or after a fall. Palpation of the gluteal muscles at the insertion on the greater trochanter and third trochanter of the femur and over the middle gluteal region reveals milder reactivity in horses with secondary strains and a much more severe response or resentment after a primary muscle injury. Upper limb flexion tests may be positive, especially if the gluteal soreness is secondary to lameness involving the hock or stifle. Ultrasonographic examination of the

Fig. 115-4 • Transverse (*left*) and longitudinal (*right*) ultrasonographic images of the palmar aspect of the pastern. Lateral is to the right and distal is to the right. There is an abnormal amount of fluid in the digital flexor tendon sheath. The lateral lobe of the deep digital flexor tendon (DDFT) is enlarged (*arrow*) with disruption of the palmar border and echogenic material palmar to this. There is a vertically orientated hypoechoic defect extending across the lateral lobe of the DDFT seen in the transverse image (*arrowhead*).

coxofemoral joint may rarely reveal increased fluid indicative of effusion, the result of synovitis or OA. Nuclear scintigraphy may support that diagnosis with IRU in dorsal or oblique images of the coxofemoral joint.

Treatment depends on the severity of the muscle injury or inflammation. Identification and appropriate treatment of the primary lower limb lameness, if present, may do much to reduce mild soreness in just a few days. Most horses with mild injury also respond well to NSAIDs, local application of moist heat, dimethyl sulfoxide, and therapeutic ultrasound. Methocarbamol (20 mg/kg orally bid) may be of benefit. Acupuncture treatments, and in horses with severe injuries local injection of corticosteroids mixed with Sarapin (mix Sarapin, prednisolone, and betamethasone in equal parts in a 12-mL syringe and inject 3 mL per site), provide pain relief. Injections are performed on either side of the spine into the sorest portions of the muscle at 5- to 8-cm intervals or at specific acupuncture sites. Injections may also be made around the region of the greater trochanter of the femur. Ultrasound-guided injection into the coxofemoral joint when synovitis or OA is suspected is recommended. Rest and a reduction in the intensity and duration of exercise also may help. Some horses may require total rest, with exercise limited to handwalking, for several weeks.

Superficial Digital Flexor Tendonitis, Tenosynovitis of the Digital Flexor Tendon Sheath, and Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendon

Superficial Digital Flexor Tendonitis

Injury to the superficial digital flexor tendon (SDFT) in a hunter or jumper is far less common and severe than in a racehorse, probably because the horse is not trained at high speeds. Injuries are more likely to result from a misstep in deep footing rather than from muscle or tendon fatigue proceeding to failure, but low-grade injuries occur frequently in top-level horses from about 10 years of age.

Recurrent injuries to the SDFT and ALDDFT may occur in association with foot pain, which changes the biomechanical stress on the digital flexor tendons (PHB). Spontaneous rupture of the SDFT also is seen in old (midteens) jumpers. Often no indication of any tendonitis is apparent before rupture. We also have seen several aged horses no longer in competition with spontaneous SDFT rupture. Geldings are overrepresented, and there may be an association between this severe trauma and hormonal imbalance.

The diagnosis of SDF tendonitis is normally not difficult, and unlike injury to the DDFT usually is not accompanied by substantial lameness, unless an acute injury occurs in the proximal metacarpal region. Lesions in the proximal metacarpal region may be a diagnostic challenge because of lack of swelling. Ultrasonographic evaluation is recommended to assess the severity, location, and extent of the injury. Several reexaminations are important to determine the rate of healing and predict the time to return the horse safely to competition.

The therapeutic goals for management of a hunter or jumper with an acutely injured digital flexor tendon are rapid reduction of the inflammatory response and elimination of edema. This is achieved with the administration of NSAIDs, low doses of corticosteroids, and diuretics. Ice, hydrotherapy, and support bandages also are used and applied as soon as possible, and often the trainer applies them before the veterinary examination. For horses with strains or injury without actual fiber tearing (type 1 or 2 lesions), peritendinous injection of corticosteroids or intralesional injection of hyaluronan may dramatically decrease the size of the tendon and produce favorable cosmetic results. The trainer must be advised not to exercise the horse and that total healing actually may be delayed slightly. After the injection the limb should be supported with a firm, modified Robert Jones bandage to prevent the return of any swelling. Tendon splitting has been indicated in horses with substantial core lesions (type 3 or 4 with a diameter greater than 0.5 cm). Ultrasound-guided intralesional injections of IRAP, PRP, or A-Cell may be of benefit

for lesions of this type and severity. The benefit of a splitting is obtained with the multiple injections required to deliver an adequate volume of product. During the procedure the material is seen going into and coming out of the tendon and causing peritendinous or subcutaneous swelling. Perhaps this produces a “lavaging” effect and removes some of the blood, serum, and inflammatory mediators from the core lesion. It is one author’s opinion that this lavaging effect is actually beneficial and that larger volumes of fluid should be used when possible (RPB). Therapeutic ultrasound after the initial phase of healing (3 to 4 weeks after injury) encourages resolution of inflammation and promotes healing. Shock wave therapy is also sometimes recommended after the injection; there is debate about frequency and intensity of treatment.

Overall, the time required for digital flexor tendons to heal sufficiently so the horse may return to jumping depends on the severity of the injury and to some degree the location of the injury. Routine SDF tendonitis takes less time to heal than an injury to the SL at the same location. A mild injury takes 3 to 4 months and a severe injury takes about 12 months to heal. Monthly ultrasonographic examinations are used to determine the physical therapy schedule and the optimum time for the horse to return to jumping. Horses often can continue to compete despite active SDFT injuries, although the lesions may slowly get worse.

Tenosynovitis of the Digital Flexor Tendon Sheath

SDFT or DDFT injury within the digital flexor tendon sheath (DFTS) frequently is seen in jumpers at any age or level of competition (Figure 115-4). Tenosynovitis also occurs without tendon injury. SDF tendonitis may result in chronic tenosynovitis and often plagues older horses. Tenosynovitis is slightly more prevalent in hindlimbs, presumably because of the strain caused by the push-off in jumping. The DFTS may be warm and swollen. Digital pressure at the proximal and distal aspects of the DFTS usually is resented. Pressure applied directly over the palmar or plantar aspect of the fetlock also may cause pain. Results of a distal limb flexion test are usually positive. Moderate effusion is usually present in horses with an acute injury, but those with chronic injuries may have a thickened, fibrotic DFTS and much less fluid. The proximal aspect of the DFTS may show effusion, yet none may occur distally in the pastern. Lack of effusion likely results from a compartment syndrome with thickening of the DFTS synovium, the SDFT, and possibly the palmar/plantar annular ligament, thus preventing the flow of fluid distally past the PSBs. However, DDFT lesions in the pastern may be associated with distention of the DFTS localized to the pastern. DDFT lesions may be core injuries readily identified using ultrasonography or marginal tears more reliably diagnosed using tenoscopy (see Figure 115-4). Lameness may vary and may be evident only after flexion of the distal aspect of the limb. Intrathecal analgesia of the DFTS usually improves lameness. Ultrasonographic examination should include the fetlock and pastern regions and reveals increased fluid, allowing the tendons and a thickened synovium to be evaluated easily. The digital flexor tendons may appear to be normal.

Therapy for horses with tenosynovitis of the DFTS varies depending on the severity of the problem and the structures involved. Antiinflammatory therapy consisting of ice, cool

water therapy, poultices, NSAIDs, and corticosteroids is effective in horses with mild primary injuries of the DFTS. In horses with more severe injuries, intrathecal injection of corticosteroids and hyaluronan is beneficial. Rest is essential. Horses with mild injuries may return to work in 1 to 2 weeks, but those with more severe injuries require more time. Good trimming and shoeing are beneficial. Transient response to treatment usually implies associated tendon injury. Horses with chronic, unresponsive tenosynovitis may require tenoscopic examination and possibly desmotomy of the palmar or plantar annular ligament.

Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendons

Desmitis of the ALDDFT is a common problem, especially in older show jumpers, and often results in sudden onset of lameness after landing over a fence, with rapid development of localized swelling. In some horses there is only mild-to-moderate swelling below the carpus on the day after jumping, with minimal to no lameness. Ultrasonography is required to determine the location, severity, and extent of the injury and subsequently to monitor healing. Treatment is similar to that for SDF tendonitis, and rapid and aggressive use of systemic NSAIDs as well as local injection of corticosteroids to control early inflammation is important. A premature return to work may result in recurrent injury and ultimately adhesion formation between the ALDDFT and the SDFT. However, many horses with mild-to-moderate strains can be managed with shortened rest periods and aggressive antiinflammatory therapy. Once inflammation has been controlled, the horse can return to work and may handle a normal workload even without meaningful healing of the injury. This depends on the severity of the injury, in particular the proportion of the cross-sectional area of the ligament affected. As long as pain and swelling are controlled, lameness is controlled and the horse can perform in many instances even without a completely healed ligament (TRO). Shock wave therapy may be useful.

Cervical Osteoarthritis and Pain

Soreness in the cervical region can seriously affect a jumper’s performance. OA of the cervical facet joints is common but may not always cause clinical signs. Muscle strain in the cervical region can also occur. Neck pain may be evidenced by an unwillingness to flex the neck laterally or dorsoventrally, by being “hard” on one side of the mouth, or by an overt forelimb lameness, which first may appear as a reluctance to advance the limb. Enticing the horse with a carrot to stretch and flex from side to side may reveal an unwillingness or limited range of motion. There may be pain on palpation. Lameness related to neck pain may appear similar to primary forelimb pain, but it is not abolished using diagnostic analgesia of the lame limb. Shoulder pain may mimic cervical pain, but analgesia of the shoulder joint or bicipital bursa may improve the lameness.

Nuclear scintigraphy is a potential screening method (RPB), but greater radiopharmaceutical uptake is frequently normally seen in the caudal cervical facet joints compared with further cranially (SJD). Comparison of left and right lateral images is crucial (SJD). Lateral and oblique radiographic images are useful for identification of OA, bearing

in mind that many horses with radiologically apparent lesions do not have clinical signs (SJD). Ultrasonography may yield additional information about joint effusion and joint capsule thickening.

Ultrasound-guided intraarticular injections of the facet joints can be used both diagnostically and therapeutically.

One author (RPB) routinely injects the affected facet joints and those immediately cranial to and caudal to the suspected joint; however, it is also his experience that regional injection also produces a positive response. Methylprednisolone acetate, 20 mg, is injected as a 3-mL solution in sterile saline at each site.

Chapter 116

Lameness in the Dressage Horse

Svend E. Kold and Sue J. Dyson

THE SPORT

Dressage is the ultimate athletic challenge in equestrian sports because it combines balance, suppleness, and power in a unique gravity-defying manner. A good horse gives the impression of athletic elegance and expressive animation. The gaits are described using terms such as *balance*, *suppleness*, and *hindlimb activity*. The first demand is that the horse be completely obedient, going wherever the rider wants and carrying out movements at his or her request. In doing so the horse has to rely on its rider, trust the rider, and accept the rider as its superior. The key to the training and development of a dressage horse from the lowest levels to International Grand Prix is gymnastic exercises, with the aim of strengthening the muscles and thereby avoiding injury to joints and tendons associated with an increased workload.

The Fédération Equestre Internationale (FEI) dressage rules state that the object of dressage is the harmonious development of the physique and ability of the horse. Through the levels of dressage training, the center of gravity of the horse and rider is placed further caudally, achieved by increasing the degree of flexion and loading of the hindlimbs, while at the same time freeing the front end of the horse to create a more airborne, uphill set of movements. This can be obtained only by increasing the power of the hindlimbs, by synchrony in movement between the forelimbs and the hindlimbs, and through the freedom of movement of the back.

In the German equestrian literature the following terms describe the aims of the correctly trained dressage horse:

- *Takt* (rhythm)
- *Lossgelassenheit* (looseness and suppleness)
- *Anlehnung* (contact with the bit)
- *Schwung* (energy and swing)
- *Geraderichten* (straightness)
- *Versammlung* (collection)

Dressage is an international sport, although it always has had its main center of excellence in Northern Europe, most particularly Germany, but in later years also in Holland, Denmark, and Sweden. More recently, teams

from Spain, the United Kingdom, and the United States have started to challenge for medal positions in international competitions. Dressage developed from the military institutes and only in the twentieth century became a truly civilian sport. Even up to the time of the Second World War, military officers participated at all the major dressage games.

In Europe the competitive sport has been divided into three levels: L, M, and S. L covers novice level (novice and elementary); M covers medium and advanced medium; and S covers Prix St Georges, Intermediare I and II, Grand Prix, and Grand Prix Special. The movements required at each of these levels reflect the horse's degree of collection, with the L classes expressing balance and freedom of movement, M classes requiring more collection and lateral movements, and S classes demanding ultimate collection to enable movements of maximum collection and suspension, such as piaffe, passage (Figure 116-1), and canter pirouettes (Figure 116-2). However, even the most skilled rider or trainer has difficulty selecting the right horses, because many promising young horses with excellent gaits fail to learn passage and piaffe, probably because of our insufficient knowledge of the biokinematics of collection.¹

Lateral movements apply specific, unique strains to different structures within the skeleton. In shoulder-in, half-pass, renvers, and travers the horse is bent evenly in its neck and body but moves on more than two tracks. In shoulder-in, the horse moves on three tracks (1, outside hindlimb; 2, inside hindlimb and outside forelimb; and 3, inside forelimb) with the body at an ideal angle of 30 degrees to the direction of movement. In travers (quarters-in) and renvers (head to the wall) the horse moves on four tracks. These movements create an unusual strain on the horse's back and pelvis and an additional twisting movement on the appendicular joints.

The increased engagement of the hindlimbs developed through collected work allows for greater storage of elastic strain energy in the hock joints and pelvis, which, via the increased lifting of the forehand, allows for high-energy movements such as medium and extended trot. The term *cadence* is associated closely with working through the back and self-carriage and requires complete freedom without which movements will be inferior. Self-carriage reflects a level of training in which the horse has learned to balance itself and its rider and additionally has developed its musculature to allow movement with greater range of freedom. This process takes time, and it is not unusual to see a degree of hindlimb gait irregularity in 4-year-old horses in the early part of training; normally this is a reflection of lack of balance and will improve with training and time.

Anlehnung (contact with the bit) is an important concept to understand, requiring the horse to move freely forward

Fig. 116-1 • Passage. Note the severe extension of the left metatarsophalangeal joint (*inset*).

Fig. 116-2 • Canter pirouette to the left. The horse intermittently takes all weight on the hindlimbs, resulting in extension of the metatarsophalangeal joints and great strain on the suspensory apparatus.

with impulsion, to take and accept the bit, and to react to it without resistance. The FEI rules require the horse to work on the bit—that is, with the front of the head positioned in, or slightly in front of, the vertical plane. In recent years the tendency has been toward training dressage horses in an over-bent fashion, with the horse's forehead behind the vertical plane, in its extreme form referred

to as *rollkur*. This is said to be a requirement for developing the trapezius and rhomboidius as well as other muscles of the shoulder and withers region and thus enabling a greater lift of the forehand via the shoulder girdle. Although this method of training contradicts the FEI requirement for the horse's forehead to be in a vertical plane, top riders are able to place the horse's head in virtually any position according to what is required. There has been considerable debate about *rollkur* being a forced and unnatural position; however, to date there is no scientific evidence to suggest that it is in any way detrimental to physical well-being, assuming that it is performed well. Moreover, some of the most successful dressage horses are trained using *rollkur* as part of the regular work program. However, as with any method of training, it is important that the horse be allowed regular stretching and rest periods to avoid muscular fatigue, which may predispose to injury.

"Contact with the bit" and "working on the bit" are terms that are frequently misunderstood. The horse must move with energy and impulsion and work through the back to enable correct contact with the bit. Stiffness in the back often results in poor and incorrect bit contact. Increased bit lathering as an indication of improved bit function is frequently seen after successful treatment of back pain. Misinterpretation of the role of the bit leads to restriction of the horse by the hands, which inevitably results in loss of action and gait irregularities. Thus inappropriate riding and training can potentially produce clinical problems.

THE DRESSAGE HORSE

Most dressage horses competing internationally are Warmbloods (WBLs) with a high proportion of Thoroughbred (TB) breeding. Dressage horses today combine the elegance

and athleticism of the TBs with the power and trainable mind of the WBLs, which have been selected for many generations for these traits. Few pure TBs reach international standard dressage. The TB has been bred to run fast or show courage jumping obstacles cross-country, which are not of great value when the rider requires complete obedience to perform movements that go as much upward and sideways as forward. Most TBs also lack the strength and quality in all three paces compared with the WBLs, in particular the walk and the trot. Most TBs do not show the same degree of natural engagement of the hindlimbs typical of many WBLs. Many of the greatest TB sires in postwar European dressage breeding (Der Löwe, Velten, and Pik As) have been neither particularly physically impressive nor equipped with more than an average trot. Previously TB stallions in WBL breeding were required to have a minimum general handicap to ensure that they had been physically and mentally strong enough to stand up to training and race consistently and reasonably successfully. Spanish horses have increased in popularity, often being easier to train than WBLs, readily learning and executing piaffe and passage, but lacking the expression and animation of the gaits of the most successful WBLs. Lipizzaner horses are rather similar and are used by the Spanish Riding School in Vienna, but are rarely used as competition horses. Mares, geldings, and stallions are used; stallions may combine competition work with breeding (usually by artificial insemination).

A dressage horse must be naturally well balanced. The head and neck must be set sufficiently high to facilitate working uphill and for easy contact with the bit to be made. The shape of the withers region is important, so that the saddle sits easily in the correct position. The dressage rider spends a lot of time sitting in the saddle in sitting trot; therefore correct weight distribution is critical.

Most dressage horses are broken at 3 or 4 years of age and begin competing in young horse classes at 5 years of age. Medium classes are reached by the age of 7 and many future Grand Prix dressage horses do a small tour at the age of 8 and 9. Once a dressage horse has reached Grand Prix level, the training predominantly involves repetition of movements, maintaining suppleness, and increasing physical power. Thus dressage horses rarely succumb to acute stress-induced traumatic injuries but are more likely to succumb to repetitive, accumulative subclinical injuries that may surface at irregular intervals. This means that with correct training and management, dressage horses can continue to compete at the highest level at an advanced age, often as old as 15 to 20 years. Many of the Lipizzaner stallions at the Spanish Riding School in Vienna are touring and performing adequately after 20 years of age.

A true link between conformation and soundness is difficult to establish, because what creates an outstanding dressage horse in terms of conformation does not necessarily create a particularly sound dressage horse, and vice versa. However, in a study of 4-year-old Swedish WBL horses, highly significant correlations were found between conformation and movement and between conformation and orthopedic health, whereas no correlation was found between the overall conformation score and competition performance.² A series of elite dressage horses had larger hock joint angles and more sloping shoulders than more average horses, whereas good forelimb movements were

characterized by a large range of flexion of the elbow and carpal joints during the second half of the swing phase. This is what previously has been referred to incorrectly as shoulder freedom. It is important that a young horse naturally places the hindlimbs well underneath itself, because the approach angle does not seem to be influenced by training.¹

Wear-and-tear lesions frequently occur because of a less-than-ideal joint and limb angulation, but many other factors influence the durability of the horse, including genetic predisposition and management conditions before skeletal maturity. The main requirement must be the ability of the horse to balance itself at all paces, because imbalance and asynchrony in movement apply unusual strains on many structures. Holmström found that a large positive diagonal advanced placement (the time difference between the hindlimb and contralateral forelimb contacting the ground) correlates with high trot scores and suggests this as being an important indicator of the horse's natural balance.¹ The positive diagonal advanced placement does not change with more collection and therefore may become a useful selection criterion. Holmström also found that a group of selected elite horses with high gait scores had significantly larger stride duration, increased hind stance phase duration, and greater diagonal advanced placement than a group of horses with low gait scores.¹ It should be noted, however, that advanced diagonal placement results in a single hindlimb bearing all the horse's weight, with increased extension of the metatarsophalangeal joint and thus increased strain on the suspensory apparatus. Medium and extended trots result in greater extension of the fetlock joints compared with working and collected trots, thus stressing the suspensory apparatus. Many talented young horses that are professionally produced for sale by auction are worked in a much bigger trot than a true working trot, which also results in high loads on the suspensory apparatus, predisposing to injury in all four limbs.

TRAINING SURFACES

Dressage horses are trained predominantly on artificial surfaces with a high degree of cushion, providing a consistency in the training surface not paralleled in other equestrian sports. All dressage competitions in mainland Europe take place on artificial surfaces, and only in England does dressage at the lower levels (L) still take place on grass. A multitude of artificial surfaces have been developed over the last 20 years. Most are based on silica sand mixed with a variety of rubber and polyvinyl chloride material, together with a binding and dust-limiting agent such as Vaseline, which ensures that such surfaces remain dust- and frost-free down to at least -5°C . This standardization of working and competition surfaces unquestionably plays a huge role in the low occurrence of many acute orthopedic problems in the dressage horse. Some trainers, however, consider constant working of repetitive movements on ideal surfaces likely to soften the limb structures and therefore recommend that the horses occasionally be jumped or hacked on less ideal surfaces to provide a stimulus for joint, tendon, and ligament adaptation and generally improve proprioception. We believe that working on a variety of

surfaces and “cross training” are helpful for maintaining both musculoskeletal soundness and a correct mental attitude.

Arena maintenance is paramount for a good surface. An effective drainage system through central and perimeter drains is also absolutely essential. Dead corners of deep sand predispose horses to momentary loss of balance and may predispose to the development of lameness. Any sudden change of surface integrity also predisposes horses to lameness. Young horses in particular work more easily and confidently on firmer modern artificial surfaces, where they can obtain a more confident grip and are less likely to fatigue. In a recent questionnaire-based study of British dressage horses the effect of arena surfaces on both lameness and undesirable gait traits such as tripping or slipping was investigated.³ The results indicated that wax-coated and sand and rubber surfaces were associated with less detrimental surface properties than sand, sand and PVC, woodchip, or grass. Woodchip was most strongly associated with the detrimental characteristic of slipping, and sand with tripping. Findings indicated that any arena surface should have a base, and limestone was recommended, with crushed concrete best avoided. In a related study, work on sand-based arena surfaces resulted in a 1.36 times greater likelihood of having lameness in the previous 2 years compared with other surfaces.⁴ However, very regular work on sand appeared to have a protective effect. Regular work on an outside arena resulted in a 0.61 times reduced risk of lameness compared with horses worked in indoor arenas. Deep, patchy, or uneven going under normal conditions and patchy, boggy, or deep surfaces in wet conditions increased the risk of lameness.

TACK

The horse must be comfortable in its tack if it is going to work optimally. Dressage saddles are designed to position the rider with a deep seat and with an extended leg position. The surface area over which the weight is distributed must be as large as possible, to avoid focal pressure points. The use of gel pads and layers of numnahs (saddle pads) is not a substitute for good saddle fit. The saddle must fit the horse and the rider and must position the rider in appropriate balance. The fit must be assessed with and without a rider. The shape of the horse's back musculature may change as the horse develops muscular strength and power; therefore a previously well-fitting saddle may become constricting. It should also be remembered that the withers and back may expand during a training session, sometimes effectively rendering the saddle too small.

Acceptance of the bit is crucial in a dressage horse. Horses vary considerably in the shape of the mouth and the sensitivity of the corners of the lips, bars, and tongue. Great variation also exists in the thickness of the tongue among horses. A slight crack in the corner of the mouth, caused by an inappropriate bit, can cause major problems with proper acceptance of the bit and the horse's willingness to work straight. At S level, horses have to compete wearing a double bridle—that is, the mouth has to accommodate both bradoon (snaffle) and curb bits. These vary greatly in shape and design, and selection of the most appropriate can be critical.

LAMENESS EXAMINATION

Examining a lame dressage horse does not differ in any great detail from examining any other equine athlete. However, examination frequently requires spending more time observing the horse being ridden, because many dressage horses reproduce the perceived problem, often no more than a resistance, only when ridden and sometimes only during certain movements. This, however, does not mean that the horse should not be examined in hand, including walking and trotting on a straight line and lunging on hard, nonslip surfaces (such as gravel) and on softer artificial surfaces. Not only does lunging on tarmac or concrete carry the risk of the horse slipping, with potentially disastrous consequences, but also in most horses such lunging alters the gait so much that it has little value in a lameness examination of an extravagantly moving dressage horse. Leading the horse on a circle at a trot also tends to alter the horse's stride. The horse does not have the freedom to move its neck and instead will set its head on the leader's hand. Many big moving exuberant dressage horses are a safety hazard either to trot in hand or to lunge and lameness is easily masked, especially if low grade. The use of sedatives such as romifidine or detomidine can be helpful, although it is an art to select the most appropriate dose. Repeated sedation may be required to permit accurate interpretation of the response to nerve blocks.

In many horses the usual rider has to be available to reproduce the described problem, if lameness is not overt. However, one should remember that just as bad riders create lameness, so good riders may hide lameness. The latter may take place completely unintentionally and may involve no more than a corrective change of point of balance of the rider through a corner, but enough that for a long time the problem may not be observable from the ground. Most veterinarians who are not competent riders are not experienced fully to appreciate the subtle differences in high-quality dressage horses, and attempting to ride the horse to better appreciate the problem may create an embarrassing situation. They are better advised to spend more time observing the horse from the ground. However, one of the authors (SJD) who is an experienced rider often finds it hugely valuable to ride a horse to be able to better understand the feel of subtle problems.

The veterinarian should not just focus on the limbs when watching the horse ridden. It is important to observe changes such as a change in lathering of the mouth, audible change in the rhythm of the stride, or even absence of teeth grinding or grunting after a particular diagnostic test. The position of the head and neck, the suppleness of movement through the back, the balance of the horse, and its ability to engage the hindlimbs in downward transitions are all important features.

For many horses the veterinarian relies heavily on the perceived observations of the rider during the lameness examination; this may involve the appreciation of subtle changes of gait, or even just an impression of a stronger rhythm or less heavy contact on the bit after a peripheral nerve block. Many riders feel through their own body if the horse is working crookedly, that is, not straight and not in complete balance, and will be able to tell the clinician if this feeling has been altered by any of the diagnostic tests.

In many horses, alternating between lunging and ridden work is useful, often going back to lunging with full tack after the horse has been ridden to see a possible difference in the gait from being ridden. Generally, horses with back pain appear worse while ridden than when lunged, with a loss of freedom and athleticism.

A useful test is to ask the rider to deliberately ride on the wrong diagonal, that is, to sit to the trot in the saddle when the inside forelimb is bearing weight. Horses with forelimb or hindlimb lameness and horses with back pain may alter the gait when the weight-bearing diagonal (of the horse) is changed. The difference in the horse's outline and attitude when changing between sitting and rising trot also may add valuable information.

It can be helpful to see the horse ridden in two 10-m-diameter circles in a figure eight. A low-grade hindlimb lameness may be highlighted as the horse changes direction, characterized by loss of rhythm and fluidity of movement, swinging the hindquarters outward, and a tendency for the inside hindlimb to cross in under the body during protraction. Careful observation of downward transitions from trot to walk may reveal that the horse does not "sit down" properly behind but stays somewhat croup high and takes slightly shortened steps behind. Low-grade unilateral hindlimb lameness may manifest only in certain movements, such as canter pirouette to the side of the lame limb. The horse may be unable to maintain the three-time canter rhythm and may try to jump out of the movement. The horse may find flying changes in canter difficult in the change toward the side of the lame limb—that is, a horse with right hindlimb lameness may perform flying changes from right to left without difficulty but perform less well from left to right, becoming croup high and/or changing late behind. Half-pass away from the lame limb may be less good—that is, a horse with right hindlimb lameness may find half-pass to the left more difficult than to the right.

In some horses lameness is created by the rider. This most commonly occurs with amateur riders who misunderstand the principles of obtaining an outline and riding the horse forward into a contact with the bit. Overrestriction by the hands, with inadequate impulsion, can create gait irregularities. Lower-level trainers are sometimes unable to appreciate these problems and may themselves be unable to work the horse better. Using a good professional rider who is not the horse's trainer to work the horse during the examination is therefore preferable. Determining definitively whether the problem is one of riding or of training or a reflection of a genuine lameness may require observing the horse over several days. A rider who sits consistently crookedly can create back pain and loss of hindlimb rhythm and symmetry. Some dressage horses are exuberant and expressive movers and also strong-willed characters that may refuse to go forward properly if ridden by an enthusiastic but less competent amateur rider, especially if the rider is somewhat apprehensive and inclined to be overrestrictive. Nappy (resistant) behavior and unwillingness to work may reflect a pain-related problem, but not necessarily so.

One should remember that not all horses are athletes. Many owners tend to think that all horses can learn to do dressage. Veterinarians must in certain situations be prepared to offer the opinion that the particular horse has too many shortcomings physically or psychologically to be

able to perform advanced dressage. A veterinarian may be able to help a horse overcome a specific problem but cannot provide missing athleticism.

The veterinarian should not forget to check the obvious. The horse may be apprehensive about taking the bit, may take irregular steps, or may be reluctant to bend properly. Wolf teeth frequently are blamed for reluctance to accept the bit properly and for irregularities in gait. Provided that a wolf tooth is immediately in front of the first upper cheek tooth and is not mobile, the tooth rarely is associated with pain.

Horses with a short poll and a relatively large mandible have difficulty in acquiring the correct degree of neck flexion. In these horses it is also important to check that airflow is not impaired. Restricted airflow is not necessarily accompanied by an audibly abnormal inspiratory and/or expiratory noise.

If a diagnosis cannot be made because clinical signs are too subtle, or if it is difficult to determine whether the clinical problem is pain related, working the horse while treating it with antiinflammatory medication (2 to 4 g phenylbutazone per day orally [PO]) for 2 to 3 weeks may be useful. If lameness returns once the medication has been withdrawn, the performance problem can be attributed to pain. The lameness also may be worse, making further investigation easier. If the horse appears to have a low-grade bilateral problem, starting by blocking one limb (forelimb or hindlimb) to see if a contralateral limb lameness immediately becomes obvious can be useful. Blocking both limbs simultaneously and then reassessing the overall freedom of movement and balance may also be of enormous value.

DIAGNOSTIC ANALGESIA

In principle, no differences exist between dressage horses and other equine athletes with regard to diagnostic analgesia. However, the horse's response should be assessed both when ridden and when trotted in hand. Because only minor irregularities in gait are often the point of investigation in lame dressage horses, it is particularly important that the conditions, including the surface, the person handling the horse, and the tempo with which the horse is lunged remain consistent throughout the lameness investigation. Starting the investigation on one surface only to change surface halfway through the nerve blocks should therefore be avoided. Indoor arenas obviously are of great assistance in terms of providing a consistent working surface in severe weather conditions.

Although the sequence of the nerve blocks in theory should be the same in all equine athletes, known common lameness sites in dressage horses often make focusing on these areas possible in order to save time and to avoid an unnecessary number of injection sites and undesirable number of clipped sites. If clipping is essential, many riders prefer that the entire limb (and contralateral limb) be clipped symmetrically rather than producing many small clipped sites in one limb.

IMAGING CONSIDERATIONS

Imaging of a lame dressage horse is no different from imaging any other equine athlete. However, the frequent

lack of overt lameness in a submaximally performing dressage horse often necessitates the use of every possible diagnostic modality available. This is particularly true for evaluation of the neck and the back, both of which are important structures for balance and coordination. These are areas in which diagnostic analgesia is less easy than in the limbs but is nonetheless important.

Radiographic evaluation of the thoracolumbar region requires fixed or semimobile radiographic equipment. Use of a Dodger-T aluminum wedge to attenuate the primary x-ray beam facilitates acquisition of high-quality images of the dorsal spinous processes.⁵

Diagnostic ultrasonography of the thoracolumbar and pelvic regions is also useful, used transcutaneously or per rectum to image the supraspinous ligament and epaxial musculature, the synovial articulations (facet joints), and the ventral aspects of the lumbosacral and sacroiliac joints.⁶ An ability to obtain high-quality images of the suspensory ligament is crucial, but according to the shape of the proximal aspect of the hindlimbs this may or may not be possible. In some horses magnetic resonance imaging (MRI) may be required for accurate diagnosis.

Nuclear scintigraphic evaluation can be particularly helpful in evaluating the thoracolumbar and pelvic regions. However, a study in clinically normal WBL riding horses showed that mild increased radiopharmaceutical uptake (IRU) in the summits of the dorsal spinous processes may be seen. Thus, as with all imaging techniques, great scientific integrity is demanded to distinguish between normal variations and pathological lesions, and results must be correlated carefully with clinical observations and with other imaging modalities.

Computerized thermographic image analysis has been reported as being helpful but in our experience is often misleading, and it is no longer used routinely.

TEN MOST COMMON LAMENESS CONDITIONS IN DRESSAGE HORSES

The conditions are listed not necessarily in strictly decreasing order of importance or frequency.

1. Proximal suspensory desmitis
 - a. Hindlimbs
 - b. Forelimbs
2. Suspensory branch lesions
3. Synovitis or osteoarthritis of the forelimb distal interphalangeal joints
4. Desmitis of the forelimb accessory ligament of the deep digital flexor tendon
5. Osteoarthritis of the centrodistal and/or tarsometatarsal joints
6. Synovitis of the middle carpal joint (possibly with palmar intercarpal desmitis)
7. Synovitis or osteoarthritis of the metacarpophalangeal and metatarsophalangeal joints
8. a. Palmar or plantar annular desmitis
 - b. Tenosynovitis of the digital flexor tendon sheath: forelimbs and hindlimbs
9. Palmar cortical stress fracture of the third metacarpal bone
10. Thoracolumbar and sacroiliac pain

In our experience many of these conditions can cause overt unilateral lameness. However, bilateral conditions

may be less easily recognized and the horse may be presented for investigation because of an insidious onset of progressive unwillingness to work or loss of quality of paces. In-depth investigation of such horses often reveals the presence of lameness in three or four limbs, with or without thoracolumbar or sacroiliac joint region pain.

PROXIMAL SUSPENSORY DESMITIS: HINDLIMBS

Probably the most important cause of lameness in dressage horses working at medium and advanced levels is proximal suspensory desmitis (PSD), although a recent study showed that nonelite dressage horses were also at high risk.⁷ The carrying capacity of the hindlimbs is increased with increased collection required for more advanced work, and movements such as piaffe, passage, and canter pirouettes (see [Figure 116-2](#)) place great strain on the hindlimb suspensory apparatus. Advanced diagonal placement, a gait characteristic of some excellent moving horses, increases stance duration and also results in the horse bearing weight on a single hindlimb, both of which may contribute to repetitive overload. Suspensory desmitis is believed to be caused by an accumulation of repetitive strains within the suspensory ligament (SL) and its proximal origin. The observation that some horses develop PSD in all four limbs suggests that some horses may have some genetic predisposition to injury.

Detection of PSD is often delayed because of its bilateral nature, which often means that overt hindlimb lameness is not present or immediately noticed by the rider. The condition may be manifested as a loss of performance, increased stiffness, change in contact with the bit, or resistances, if bilateral. If unilateral, problems may arise with specific movements such as canter pirouette or flying changes. In our experience dressage horses tolerate hindlimb PSD less well than show jumpers or event horses, probably because the temperament of the horses is different and the enjoyment of jumping can override low-grade pain.

Accurate diagnostic nerve blocks therefore are required to reveal lameness. When no obvious lameness is present, lameness may be created subsequently in the contralateral hindlimb by diagnostic analgesia of either of the hindlimbs. A negative response can be misleading, and it is often necessary to block both hindlimbs simultaneously, after which there may be a substantial improvement in gait. Direct palpation of the region often fails to indicate a problem because of the deep location of the proximal aspect of the SL. The clinical diagnosis is confirmed by positive subtarsal analgesia (of the deep branch of the lateral plantar nerve), together with negative intraarticular analgesia of the tarsometatarsal (TMT) joint. In some horses PSD and distal hock joint pain occur together and additional intraarticular analgesia of the TMT joint is required for complete resolution of lameness. In other horses, especially those with lesions involving the most proximal aspect of the SL, a tibial nerve block is required to abolish lameness. In some horses, usually those with bilateral PSD, there is coexistent sacroiliac region pain. There may be substantial clinical improvement after bilateral subtarsal nerve blocks, but the quality of the paces, especially canter, and the balance of the horse may not be normal. Further improvement is seen after infiltration of local anesthetic solution around the sacroiliac joint regions. In some young horses, often those that have been professionally produced and

sold through public auction in continental Europe, that have developed problems within the first few months of purchase, resolution of hindlimb lameness may reveal a forelimb lameness, often bilateral, also the result of PSD.

Extensive ultrasonographic and radiological changes often reflect a chronic and long-standing problem. Ultrasonographic images may reveal enlargement of the proximal aspect of the SL in both transverse and longitudinal planes, with areas of reduced echogenicity, most often involving one or both of the dorsal quadrants of the ligament. However, in other horses ultrasonographic abnormalities may be much more subtle; areas of increased echogenicity may reflect chronic fibrosis. Radiological diagnosis requires high-quality radiographs of the proximal metatarsal region; dorsoplantar and lateromedial images are the most useful. Irregularity of the proximal plantar cortex of the third metatarsal bone (MtIII) may occur in the region of the origin of the SL, with a varying degree of endosteal new bone resulting in increased radiopacity of the trabecular bone over a distance of up to 5 cm. On dorsoplantar images this may be seen as a centrally or laterally positioned area of increased radiopacity within the trabecular metaphysis of the MtIII. One should remember, however, that such radiological changes may be present in an asymptomatic horse because of previous problems (either subclinically or clinically manifested), leading to the risk of a false-positive diagnosis. Diagnosis should never be based only on radiological evaluation.

Occasionally, nuclear scintigraphy can be useful in horses with early desmitis in which no radiological changes are present and subtle, equivocal abnormalities are detected with ultrasonography. IRU may occur in the proximoplantar aspect of the MtIII in bone phase (delayed) images. Pool phase (soft tissue) images are rather insensitive, and not all horses have associated IRU in the proximal plantar metatarsal region. Thus a negative bone scan does not preclude PSD. Moderate-to-intense IRU usually reflects enthesesous reaction. MRI may be required for definitive diagnosis.

Treatment of this condition is often frustrating because of the chronic nature of the problem at the time of its detection. However, in well-conformed young horses with recent onset of clinical signs, rest may be all that is required, with a careful progressive resumption of work after approximately 3 months. Corrective trimming to restore foot balance is important; shoeing using egg bar shoes provides some support in horses with hyperextension of the fetlock joint. In horses with chronic injuries prolonged rest (3 to 6 months) often provides a disappointing response, and a controlled exercise program may be more successful. Periligamentous, subfascial injection of hyaluronan plus a corticosteroid (e.g., 40 mg of methylprednisolone acetate or 10 mg of triamcinolone acetonide) is now used frequently and is believed to provide an initial reduction in inflammation to enable a reasonably pain-free walking program to be initiated. This frequently is continued for as long as 12 weeks before slow, balanced trotting on a good surface is initiated.

The ultrasonographic appearance of the SL often changes little, even in horses that are returned successfully to full training. Egg bar shoes are often removed when normal training is initiated, because many riders believe that they provide too much breaking action on ground impact of the hindlimbs. The likelihood of recurrence of

PSD is high, and special care should be taken not to overwork the horse on deep or holding surfaces or to change suddenly to a different surface. Modification of the training program is often required, particularly in terms of avoiding a fatiguing training session in deep or loose surfaces. Medium and extended paces should be avoided as far as possible during training.

Some horses have chronic lameness that fails to respond to therapy. Some horses with mild or moderate ultrasonographic lesions respond to serial shock wave therapy or radial pressure wave therapy, initially using three treatments at 2-week intervals. There is often substantial improvement in lameness and ultrasonographic appearance of the ligament. Further treatments can be given if required.

Ultrasound-guided injection of core lesions with platelet-rich plasma (PRP) has recently shown encouraging results. Neurectomy of the deep branch of the lateral plantar nerve, with or without fasciotomy, has a role in horses that fail to respond to medical management or in horses with a long-term history of suboptimal performance. Concurrent medication of the tarsometatarsal joint is required for complete resolution of lameness in some horses. The presence of a straight hock conformation or hyperextension of the hind fetlock is a poor prognostic indicator.

In view of the relatively common occurrence of PSD becoming apparent in young horses soon after purchase after preparation for sale by auction, one of the authors (SJD) recommends a 3-month period of rest after purchase and then introduction of a graduated work program to try to prevent PSD becoming clinically apparent.

PROXIMAL SUSPENSORY DESMITIS: FORELIMBS

Forelimb PSD is seen more often than hindlimb PSD in younger horses and may result from hyperextension of the carpus in extravagantly moving horses, in particular horses volunteering extended trot. PSD often results from the horse working on less than ideal surfaces. Lameness is often unilateral and acute in onset but is sometimes bilateral. Most sound horses resent firm manual squeezing of the body of the SL but the proximal region of the SL is difficult to access by palpation; therefore local analgesic techniques are required to verify the source of pain.

In horses with peracute PSD, slight swelling in the proximal metacarpal region may occur, but this often resolves within 24 hours. The horse may react to firm pressure applied over the proximal aspect of the SL. Lameness may be transient unless the horse is worked again. In these horses, the veterinarian relies on a history of acute-onset lameness that is usually worse with the affected limb on the outside of a circle. However this is not pathognomonic for PSD. Lameness is often easier to feel (by a rider) than to see from the ground. In some horses lameness is never apparent either in hand or on the lunge but is only seen ridden, incongruously with the lame limb on the inside of a circle. The appearance of lameness may be influenced by the diagonal on which the rider sits.

Lameness may be worse after palmar (abaxial sesamoid) nerve blocks, probably because the horse loses some proprioceptive information from the foot and therefore is less able to protect the loading of the suspensory apparatus.

Some improvement is often seen after perineural analgesia of the palmar and palmar metacarpal nerves at the junction of the proximal two thirds and distal one third of the metacarpal region, either because of proximal diffusion of local anesthetic solution or the presence of pain in the more distal aspects of the suspensory apparatus. Lameness is usually substantially improved or resolved by blocking the lateral palmar nerve or the palmar metacarpal nerves at subcarpal level. However, in some horses an ulnar nerve block is required. Because of the close proximity of the middle carpal joint capsule, horses with a positive response to subcarpal analgesia should later be evaluated with intraarticular analgesia of the middle carpal joint to exclude articular pain from the carpus.

Radiography is frequently of little or no value in dressage horses with forelimb PSD. Ultrasonography is required to confirm the diagnosis. Use of a virtual convex array transducer and/or acquisition of images obtained while the limb is flexed may be required to identify abaxial lesions. Because subtle lesions may be present and may be a reflection of a previous pathological condition (possibly subclinical), high-quality ultrasonographic images of both limbs are required for comparison, together with knowledge of normal variations. Lesions vary from subtle enlargement of the proximal aspect of the SL with normal echogenicity to large areas of reduced echogenicity. In some young horses no ultrasonographic abnormalities have been detected, but MRI has confirmed the presence of PSD.

Rest, often for 12 to 16 weeks, together with a controlled, ascending walking program (in hand, using a horse walker, or ridden) is the treatment of choice. Careful trimming to restore foot balance is crucial. Intralesional injection using 2 mL of a polysulfated glycosaminoglycan (PSGAG) or PRP may also be tried.

The prognosis is good in horses with early PSD, provided that the horse is managed carefully subsequently, avoiding the medium or extended trot in training. In horses with chronic PSD the risk of recurrence is moderately high. Shock wave therapy has been useful in treating some of these horses. In others injection of mesenchymal stem cells or desmoplasty has produced a successful outcome. In some horses the ultrasonographic appearance may not change substantially, despite a favorable clinical response to treatment, leading to later risk of a false-positive diagnosis in an asymptomatic horse.

DESMITIS OF THE SUSPENSORY LIGAMENT BRANCHES: FORELIMBS AND HINDLIMBS

Desmitis of a branch of the SL is often acute in onset and results in palpable enlargement of the suspensory branch and often moderate lameness. Occasionally, both medial and lateral branches are involved in a hindlimb. The branch is painful to palpation. Diagnosis is confirmed by ultrasonography. Enlargement of the branch is often accompanied by periligamentous fibrosis characterized by subcutaneous echogenic material. There is often a central (sometimes eccentric) hypoechogenic or anechogenic core lesion. The interface between the ligament branch and the proximal sesamoid bone (PSB) may be disrupted. This is best seen on longitudinal images and merits a more guarded prognosis. If both branches in a hindlimb are involved, echogenic material may be visible between the branches.

The PSBs may or may not show radiological evidence of enthesopathy, with parallel linear opacities extending from the palmar or abaxial margin. Dystrophic mineralization within the SL branch is occasionally seen on ultrasonographic and radiographic images.

Treatment is prolonged rest (4 to 6 months) with a slow return to exercise. Intralesional injections using 1 mL of a PSGAG may be tried but generally have met with disappointing results. Counterirritation (pin firing) has been tried on horses with old, indurated lesions associated with chronic lameness, but again generally with disappointing results. Some horses have responded to intralesional treatment with β -aminopropionitrile fumarate. Encouraging results also have been obtained recently with shock wave therapy (three treatments at 2-week intervals), combined with a controlled walking exercise program for 3 to 4 months. However, the presence of extensive periligamentous fibrosis is a poor prognostic indicator.

The risk of recurrence is high. Any predisposing causes such as limb deviations or lateromedial imbalance of the feet should be corrected or at least adjusted.

SYNOVITIS OR OSTEOARTHRITIS OF THE DISTAL INTERPHALANGEAL JOINT

Pain arising from the distal interphalangeal (DIP) joint is a frequent diagnosis in all sports horses. The unique anatomical position of the DIP joint, with the forces distributed on it through the rigidity of the hoof capsule and the forward thrust of the deep digital flexor tendon (DDFT) and the navicular bone during weight bearing and limb protraction, are likely to be contributory factors. Lateral-to-medial imbalance of the foot also contributes to the joint trauma in many horses.

The diagnosis is made by comparing the response to intraarticular analgesia with that of (minimal volume, 0.5 mL per branch) perineural analgesia of the palmar digital and palmar (abaxial sesamoid) nerves as well as intrasynovial analgesia of the navicular bursa. The interpretation of the response to intraarticular analgesia is not black and white, and the clinician must learn to build up a picture of a composite, often complicated distal forelimb lameness. Recent studies have confirmed that intraarticular analgesia of the DIP joint is not specific and can influence pain associated with the navicular bone, distal phalanx, DDFT, and even subsolar tissues. A rapid (within 5 minutes) positive response to a small volume (maximum of 6 mL) of local anesthetic solution may be a good indicator of the possible response to subsequent intraarticular medication. A good response to subsequent treatment requires at least 75% clinical improvement after intraarticular analgesia, together with absence of relevant radiological changes involving the DIP joint or the navicular bone.

Radiological changes usually involve the extensor process of the distal phalanx and the dorsoproximal margin of the navicular bone. One should remember that considerable variation exists in the shape and size of the extensor process between limbs and within sound horses. Minor modeling changes may not be of clinical significance. Small, mineralized fragments proximal to the extensor process may be seen incidentally. Large fragments may require surgical removal to prevent secondary osteoarthritis (OA).

Intraarticular medication using a number of individual drugs or a combination of drugs has given encouraging results, although results vary among clinicians and populations of horses. Horses with recent onset of usually unilateral lameness with palpable distention of the DIP joint capsule may respond favorably to 10 mg of triamcinolone acetonide or up to 40 mg of methylprednisolone acetate, combined with a short period of controlled walking exercise (e.g., 2 weeks on a horse walker) followed by 2 weeks of ridden walking. Injection with hyaluronan probably will provide a similar response in such horses. However, in horses with more chronic lameness, the response to corticosteroids is less favorable, and the most successful long-term results have been seen after a triple series of intraarticular injections of a PSGAG.⁸ PSGAGs received some negative press after a research study in North America in 1989 suggested that PSGAGs have a potentiating effect on a subinfectious dose of *Staphylococcus aureus* in a joint. Subsequently, this preparation has been used sparingly intraarticularly and in many horses only in combination with intraarticular amikacin. We have not seen any negative reaction (inflammatory or infectious) to numerous intraarticular injections of PSGAGs and do not use systemic or intraarticular antibiotics. Strict asepsis and a skillful technique are essential. Because of its distal location in the limb, we recommend that DIP joints always be bandaged for at least 24 hours after injection. Eighty-two percent of dressage horses returned to soundness after PSGAG medication of the DIP joint, compared with 65% in a similar-sized group of horses competing in cross-country jumping.⁸ In most horses the initial triple injection proved adequate, and additional injections in horses successfully treated using this technique were rarely needed.

Autologous conditioned serum containing interleukin-1 receptor antagonist protein (IRAP) has proved beneficial for management of horses with DIP joint or navicular bursa pain.

Corrective shoeing by improving the foot-pastern axis and reestablishment of correct hoof balance should always be combined with intraarticular medication, but changes should be performed slowly. Heart bar shoes often are used for an initial 3- to 6-month period.

DESMITIS OF THE ACCESSORY LIGAMENT OF THE DEEP DIGITAL FLEXOR TENDON: FORELIMBS

Desmitis of the accessory ligament of the DDFT (ALDDFT) frequently occurs as an acute injury associated with sudden onset of lameness and palpable inflammation (heat and swelling) in the proximal one third or one half of the metacarpal region. Overextension of the carpus caused by imbalance in young horses or resulting from imperfect working surfaces is often believed to be a contributory cause.

The diagnosis is confirmed by ultrasonography in both transverse and longitudinal planes. There is often substantial enlargement of the ALDDFT, together with loss of definition of the margins and areas of reduced echogenicity. A definite, hypoechogenic core lesion is recognized infrequently.

Horses with desmitis of the ALDDFT respond better to a controlled ascending walking exercise program than to complete box rest. Controlled walking for 3 to 6 months often is required in horses with severe desmitis, despite the initial lameness often resolving considerably sooner. The

risk of recurrence is moderately high. Local invasive treatment of desmitis of the ALDDFT seldom has been rewarding, although some horses have responded favorably to treatment with β -aminopropionitrile fumarate and more recently with PRP.

DESMITIS OF THE ACCESSORY LIGAMENT OF THE DEEP DIGITAL FLEXOR TENDON: HINDLIMBS

Desmitis of the proximal aspect of the ALDDFT of hindlimbs results in acute-onset lameness usually associated with soft tissue swelling in the proximoplantar aspect of the metatarsal region. Diagnosis is confirmed by ultrasonographic examination; it is important to examine the limb from the plantaromedial aspect; otherwise, lesions may be missed (see Figure 71-3).

OSTEOARTHRITIS OF THE CENTRODISTAL AND TAROMETATARSAL JOINTS

Lameness or poor performance (e.g., inability to collect in order to perform piaffe or passage) associated with pain arising from the centrodistal (CD) or TMT joints occurs frequently in dressage horses. Likewise, a horse with an outstanding freedom of movement in the trot may have an unexplainably poor canter associated with distal hock joint pain. In collected paces there is increased tarsal loading and joint compression,⁹ which may predispose to tarsal injury in dressage horses. The pattern of subchondral bone thickness in the distal tarsal bones reflecting loading pathways is different in elite performance horses compared with general-purpose horses.¹⁰ This may be related to circling and other specific movements, and potentially predisposes to pathological change.

A poor correlation exists between the clinical signs, including response to intraarticular analgesia of the TMT and CD joints, and the radiological appearance of these joints. Many dressage horses have confirmed pain from the joints but have fairly equivocal, if any, radiological changes. One should remember that the degree of joint collapse and osseous ankylosis always is underestimated from radiographs because of the curvilinear nature of the joints and the low radiodensity of immature bone bridging the joint centrally. Nuclear scintigraphy may be a sensitive indicator of increased bone modeling in the absence of radiological abnormalities or in horses with equivocal changes and also can be helpful in horses with subtle lameness, when the response to local analgesic techniques is difficult to interpret. Alternatively, diagnostic medication with intraarticular corticosteroids may be helpful.

Pain is often bilateral, and the presenting problem is often shortening of the hindlimb stride and an inability to collect, rather than overt lameness. An advanced horse may show irregularities of rhythm in piaffe and passage. Clinical signs mimicking back pain, rather than overt lameness, may be present.

Most horses respond to intraarticular analgesia of the TMT and CD joints, although occasionally a better response is seen after fibular and tibial nerve blocks or after treatment of the joints. Intraarticular analgesia of the TMT joint and the response to subtarsal analgesia should be compared. In horses with advanced radiological changes, false-negative responses to intraarticular analgesia may occur.

Horses with few or no radiological changes may respond satisfactorily to intraarticular medication with a corticosteroid (e.g., up to 40 mg of methylprednisolone acetate or 10 mg of triamcinolone acetonide), IRAP, or 1 mL of a PSGAG if lameness is of longer duration. Medical treatment often is combined with a program of controlled walking exercise for 2 to 4 weeks (pending response to treatment), together with alterations of the shoeing. Horses that tend to plait or swing the affected limb axially during protraction may benefit from a lateral extension shoe, which may help to normalize posture and hindlimb gait pattern with an additional effect on secondary back pain.

Repeated medication of the joint(s) may be required at monthly or quarterly intervals. A longer response may be achieved by combined use of corticosteroids and hyaluronan.

Additional PSGAG medication given intramuscularly on a weekly basis (500 mg/mL, 7 times 5 mL) may be beneficial. Tiludronate infusion has given poor results. Glucosamines and chondroitin sulfate given orally on a daily basis are often administered, but clinical efficacy remains largely unproven.

If substantial radiological changes are present, the joint is changed irreversibly, and the horse fails to respond to repeated intraarticular medication, fusion of the joints by surgery or by intraarticular injection of sodium monoiodoacetate or ethyl alcohol can be considered, but the prognosis for high-level dressage is guarded.

SYNOVITIS OF THE MIDDLE CARPAL JOINT

Lameness associated with pain in the middle carpal joint has been seen in many dressage horses, in particular young horses that still may be struggling to establish balance and synchronicity in all paces with the additional weight of the rider. Lameness is often mild and most frequently unilateral, being most noticeable when the limb is on the outside of a 10-m diameter circle. Intermittent hyperextension of the carpus, often on a tight circle, is believed to be involved.

If the response to analgesia of the middle carpal joint is positive, the proximal SL should be examined by ultrasonography to preclude injury.

Usually, no radiological or ultrasonographic changes are present involving the middle carpal joint. Arthroscopy of the middle carpal joint sometimes reveals damage to one (most frequently the medial) or both of the palmar intercarpal ligaments, which show edema, petechial hemorrhage, and fraying of superficial fibers.

Most horses respond well to intraarticular medication using a triple series of 1 to 2 mL of a PSGAG given 8 days apart, or treatment with short-acting corticosteroids combined with hyaluronan. Six to 8 weeks of ridden walk or on a horse walker should be followed by a modified training program for at least another 3 months.

SYNOVITIS OR OSTEOARTHRITIS OF THE METATARSOPHALANGEAL AND METACARPOPHALANGEAL (FETLOCK) JOINTS

Fetlock joint disease is not a common problem in dressage horses and certainly does not seem to be as common in this type of equestrian sport as in others. The absence of

galloping across often firm and irregular surfaces associated with cross-country jumping is a likely explanation.

The diagnosis is confirmed by palpation and intraarticular analgesia. In the absence of radiological changes, intraarticular medication using a corticosteroid (e.g., 10 mg of triamcinolone acetonide), together with 2 mL hyaluronan in horses with synovitis, or 1 mL of PSGAG in horses with more long-standing OA, frequently has proved successful. IRAP treatment has also proven successful. Generally the response to medication is good and the likelihood of recurrence is low in the forelimbs. The response is poorer in hindlimbs. Horses with radiological abnormalities consistent with OA warrant a more guarded prognosis.

PALMAR OR PLANTAR ANNULAR LIGAMENT DESMITIS

Desmitis of the palmar (plantar) annular ligament (PAL) occurs more commonly in forelimbs than in hindlimbs and usually results in acute-onset lameness. The PAL has localized heat and is palpably enlarged, with pain elicited by firm pressure. Mild distention of the digital flexor tendon sheath (DFTS) may occur. Diagnosis is confirmed by ultrasonography. The PAL is thickened, with a diffuse reduction in echogenicity or focal hypoechogenic areas. Horses with acute desmitis usually respond well to box rest and controlled walking exercise for 3 months. In the acute phase, nonsteroidal antiinflammatory drugs (e.g., phenylbutazone 2 g bid PO for 5 days) are beneficial. If associated with a degree of synovitis of the DFTS, intrasynovial treatment of the DFTS with a corticosteroid may assist in resolution of lameness.

Radial pressure wave treatment has also proven a useful alternative to surgery. Tenoscopic resection of the ligament is reserved for horses not responding to conservative management.

TENOSYNOVITIS OF THE DIGITAL FLEXOR TENDON SHEATH

Tenosynovitis of the DFTS often results in sudden-onset lameness associated with distention. Some horses have long-standing distention of the DFTS without lameness (windgalls), especially in the hindlimbs, but subsequently develop clinically important tenosynovitis. Constriction of the DFTS by the PAL may be apparent. Lameness may vary from mild to severe and usually is accentuated by distal limb flexion. If distention of the DFTS is acute in onset, then local analgesia is usually unnecessary. However, if distention of the DFTS has been present for some time, then the source of pain should be confirmed by local analgesia. Intrathecal analgesia of the DFTS usually results in substantial improvement in lameness but often does not alleviate it fully. Perineural analgesia of the palmar or plantar (midcannon) and palmar metacarpal or plantar metatarsal nerves usually eliminates lameness. Improvement sometimes is seen after perineural analgesia of the palmar nerves at the level of the PSBs. Excluding the metacarpophalangeal joint as a potential source of pain by intraarticular analgesia may be necessary.

Ultrasonographic examination should be performed in the metacarpal and pastern regions. Usually an abnormal amount of fluid within the DFTS allows better visibility of

the normal synovial plicae extending from the medial and lateral margins of the DDFT in the distal metacarpal region and the synovial fold on the palmar aspect of the DDFT in the pastern region. These should not be mistaken for adhesions or tears of the DDFT. In horses with chronic tenosynovitis, the DFTS wall may be thickened, with echogenic bands within the DFTS representing adhesions. Ultrasonography frequently underestimates adhesion formation. The superficial digital flexor tendon (SDFT) and DDFT should be inspected carefully, because tenosynovitis may be secondary to a primary pathological tendon condition. Lesions of the DDFT occur more commonly, either as ill-defined core lesions or marginal tears, most frequently of the lateral margin. The latter can be difficult to detect by ultrasonography. Enlargement of the cross-sectional area of the tendon compared with the contralateral limb suggests a lesion, which may be confirmed only by tenoscopic evaluation of the sheath. Mineralization within the DDFT warrants a guarded prognosis. Horses with early tenosynovitis without adhesions or detectable lesion of the DDFT respond well to intrasynovial administration of a corticosteroid (e.g., 10 mg of triamcinolone acetonide) or 2 mL of hyaluronan, together with a pressure bandage and box rest with handwalking for 4 to 6 weeks. Horses with small core lesions of the DDFT may respond satisfactorily to conservative management, but those with large core lesions have a more guarded prognosis. However, ultrasound-guided injection of cultured mesenchymal stem cells has yielded encouraging results in a small number of horses.

If the horse fails to respond adequately to medical therapy, then surgical exploration is warranted. Tenoscopic evaluation should be performed to evaluate the extent of adhesion formation and to detect longitudinal tears in the medial or lateral margins of the DDFT, which may extend proximally under the manica flexoria. Resection of intrasynovial adhesions and lavage, with or without resection of the PAL, may resolve the problem. Horses with lesions of the DDFT that may be debrided warrant a more guarded prognosis. Surgery is frequently followed by intrasynovial injection of 2 mL of hyaluronan, repeated 4 to 6 weeks later to reduce inflammation and to try to prevent adhesions from reforming.

The response to surgery depends on the chronicity of the problem, the amount of intrasynovial adhesions, and the presence of lesions of the DDFT. Horses with lesions involving the forelimbs appear to have a better prognosis than those involving the hindlimbs. Surgery is accompanied by 8 to 12 weeks of absence from training, although controlled walking in hand or on a horse walker is essential to try to stretch any adhesions that reform.

PROXIMAL PALMAR CORTICAL STRESS FRACTURE OF THE THIRD METACARPAL BONE

Proximal palmar cortical stress fracture of the third metacarpal bone (McIII) occasionally is seen in dressage horses, especially young horses, with an acute onset of moderate-to-severe lameness. Hyperextension of the carpus, imbalance, and limb asynchrony in immature horses are believed to be contributing factors.

The diagnosis is sometimes suspected when pain is induced by digital pressure on the palmaroproximal aspect

of the McIII. When the horse trots on a firm surface, the lameness tends to increase the farther the horse trots. If the horse turns and then trots again, lameness appears to be improved and then increases again. Lameness usually is improved substantially by perineural analgesia of the palmar metacarpal nerves in the subcarpal region. If the fracture extends into the carpometacarpal joint, improvement also may be seen after intraarticular analgesia of the middle carpal joint.

On radiographs a fracture may be recognized on a dorso-palmar image as a linear radiolucent line, usually in the medial aspect of the McIII and extending up to 8 cm, possibly with surrounding increased radiopacity. In some horses a fracture line cannot be seen, although increased radiopacity is present. In some horses no radiological abnormality is identified. In these horses, the diagnosis is confirmed by nuclear scintigraphy, with focal intense IRU in the proximal palmar aspect of the McIII. Alternatively, MRI can be used but is generally unnecessary.

Treatment is complete box rest for 6 weeks, followed by 6 weeks of controlled walking exercise. The prognosis is good, and the likelihood of recurrence low.

THORACOLUMBAR AND SACROILIAC PAIN

Thoracolumbar and sacroiliac region pain are frequent causes of reduced performance in dressage horses. In a questionnaire survey concerning British dressage horses, so-called back pain occurred in 25% of horses in a 2-year period.⁴ However, in a high proportion of horses lameness was subsequently identified. It is therefore important to appreciate that the appearance of back stiffness and recognition of back pain may reflect an underlying lameness, which is sometimes subclinical. Although caudal thoracic back muscle soreness may be secondary to primary hindlimb lameness, primary back pain does occur commonly and is usually not associated with overt lameness, although poor hindlimb impulsion or intermittent hindlimb gait irregularity can be seen. Sacroiliac joint region pain often develops secondarily to hindlimb PSD. The horse may have a history of unwillingness to perform certain movements, stiffness, loss of impulsion and cadence, loss of action, or being less easy to work in a correct outline. Sometimes bucking or other nappy (resistant) behavior remain the only clinical observations. The horse usually moves better on the lunge than when being ridden. The most common causes of back pain include the following:

1. An ill-fitting saddle
2. The rider sitting crookedly
3. Primary muscle spasm
4. Impingement of dorsal spinous processes in the mid-thoracic to cranial lumbar regions
5. OA of the synovial articulations (facet joints) in the region of the thoracolumbar junction
6. Sacroiliac disease
7. A combination of lesions in the thoracolumbar and sacroiliac regions

Definitive diagnosis of the cause of back pain can be a diagnostic challenge. It may be helpful to work in conjunction with a skilled physiotherapist or chiropractor. Liaison with an experienced high-quality saddle fitter may also be valuable. Obvious causes such as ill-fitting saddle or the position of the rider should be eliminated first before

proceeding with more sophisticated diagnostic tests such as radiography, ultrasonography, nuclear scintigraphy, and thermography. If back muscle tension or spasm is obvious, assessing the response to treatment using physiotherapy (e.g., manipulation and therapeutic ultrasound) or anti-inflammatory medication may be worthwhile before further investigation.

Thermography provides pictorial images of the surface temperature of the body, which gives a physiological identification of changes in tissue perfusion or sympathetic neuromuscular dysfunction. Thermography is a useful tool to demonstrate to an owner the effect of a poorly fitting saddle or the rider sitting crookedly and also may be useful in identifying acute superficial ligament or muscle injuries.

Nuclear scintigraphy may be more sensitive than radiology for detecting lesions in the thoracolumbar or sacroiliac regions, but radiology potentially gives more structural information, such as the proximity of the dorsal spinous processes. It is important to verify the clinical significance of any lesions identified by infiltration of local anesthetic solution whenever possible. If dorsal spinous processes are extremely crowded, injecting between them may not be possible, but injecting around them (20 to 50 mL of

mepivacaine) usually results in substantial improvement within 15 minutes of injection, although this may confirm "back pain" rather than pain specifically arising from impinging dorsal spinous processes.

Ultrasound guidance is necessary for infiltration around synovial articulations.

Treatment is aimed at removing any predisposing factor and control of pain. Local infiltration with corticosteroids (e.g., methylprednisolone acetate combined with mepivacaine) or Sarapin is successful in some horses. If pain associated with impinging dorsal spinous processes fails to be controlled by medical management, surgical treatment should be considered. Infiltration of corticosteroids, Sarapin, or a sclerosing agent, P2G (Martindale Pharmaceuticals, Romford, Essex, United Kingdom), around the sacroiliac joints produces clinical improvement in some horses with pain associated with these joints. Acupuncture can be a useful adjunctive therapy for pain management. The daily work pattern and training methods used by the rider and trainer should also be reviewed for successful long-term management. Regular lunge work in a Pessoa may be of benefit. Exercises to increase core muscle strength are important. Slow warm-up in a pace that the horse finds easy is also valuable.

Chapter 117

Lameness in the Three Day Event Horse

Andrew P. Bathe

SPORT OF EVENTING

The sport of eventing generally is considered the most all-around test of a horse's athletic ability, and therefore the horses tend to be jacks-of-all-trades rather than excelling in any one particular area. The competition consists of three disciplines, namely dressage, show jumping, and cross-country, with the latter being the most influential phase. The Three Day Event or *Concours Complet International* (CCI) is the pinnacle of the sport (Figure 117-1) and is run over 4 days: 2 days of dressage, followed by a day for the speed and endurance phases and a day of show jumping. In the traditional long-format event the speed and endurance test consists of roads and tracks at trotting speed, a steeplechase, and the actual cross-country phase over fixed obstacles. This is a severe athletic test, and horses normally compete in only two or maximally three such competitions in a year. Since 2004 a "short format" Three Day Event has been introduced, which excludes the steeplechase and endurance phases but leaves the cross-country phase. This is cheaper to stage and potentially requires a smaller site on which to run the competition. At CCI**** level the course must be 6720 to 6840 m in length, with

up to 45 jumping efforts at an optimum speed of 570 mpm, to therefore be completed within 11 to 12 minutes. It has resulted in some horses competing in three or occasionally four such competitions in one year.

CICs (international One Day Events), One Day Events or Horse Trials, compress the same disciplines into a shorter time frame but without the roads and tracks and steeplechase phases. The distance and thus time for the cross-country phase are also much shorter, and there are fewer jumping efforts, so that many such competitions may be completed in a season. For most advanced horses, One Day Events are used as training for the Three Day Events, although a large number of recreational competitors aspire to compete in only One Day Events. There are an increasing number of relatively high-prize money CICs, encouraging international level horses to compete more frequently. The emphasis of this chapter is the Three Day Event horse, because the extreme demands placed on this horse give characteristic patterns of lameness, whereas the novice One Day Event horse can be considered a standard riding club or recreational horse from a veterinary point of view.

Eventing is an established Olympic sport and a substantial equine industry. The highest grade of competition is the four-star event (CCI****). Traditionally these have been the English events of Badminton and Burghley, although there are now more elite level competitions around the world including Lexington, Kentucky, United States and Luhmühlen, Germany. The sport has a high-risk element for rider and horse, and a noticeable recent trend has been to try to make courses safer, with the introduction of fences with frangible pins to try to minimize the frequency of rotational falls.

The sport includes substantial veterinary involvement. During a Three Day Event, the horse is examined by the

Fig. 117-1 • Example of a cross-country fence at CCI**** level. (Courtesy Kit Houghton Photography, Bridgewater, Somerset, United Kingdom.)

official veterinarians on arrival, the day before commencing the dressage, before and after the cross-country, and the morning before show jumping. The horse must be deemed fit to compete—that is, the horse must be sound—throughout the competition, and thus any orthopedic disorders are of great clinical significance. A mild degree of hindlimb gait asymmetry may be acceptable to the Inspection Panel, but any noticeable forelimb lameness normally is not permitted.

HORSE TYPES

Because the Three Day Event places great emphasis on the horse's speed and stamina, there is a preference toward the Thoroughbred (TB) or predominantly TB crossbreeds. A substantial proportion of horses are of uncertain or unknown breeding. Exceptions have been notable, but Warmbloods and classic Irish hunter types normally do not have the endurance required at the top level. Such horses often may do extremely well at the lower levels, however, because they move and jump better than the pure TB. [Figure 117-2](#) demonstrates what could be considered the ideal modern eventing stamp, a highly successful New Zealand TB. A horse's ability and mental aptitude are the most important determinants, and other body types are

Fig. 117-2 • An ideal modern eventing stamp. This 16.1-hand-high New Zealand Thoroughbred gelding was an individual Olympic and World Championship gold medalist. (Courtesy Badminton Speciality Feeds, Oakham, Rutland, United Kingdom.)

Fig. 117-3 • Example of a successful but tall and hunter-bred horse. This 17-hand-high gelding Thoroughbred-cross Irish draft horse was a Badminton CCI**** winner and Open European Championship Team gold medalist. (Courtesy Kit Houghton Photography, Bridgewater, Somerset, United Kingdom.)

successful ([Figure 117-3](#)). An average ideal size would be 16.2 hands, but the rules are not hard and fast. The short-format Three Day Event has perhaps slightly reduced the emphasis on pure galloping ability, and because the courses usually have the same number of jumping efforts, sometimes in a shorter course, there is a need for the horses to be quick and nimble.

The financial value of event horses is considerably lower than that of racehorses, show jumpers, or dressage horses, so any horse with outstanding ability in one of these phases is likely to be used in that sport first. If the horses do not

succeed, then they may be tried as potential event horses. These horses bring with them any injuries they may have accumulated, but because of the different stresses imposed during eventing, this may not be a problem. For example, event horses tolerate low-grade carpal pathological conditions from previous race training. A small number of horses are bred specifically for eventing. Stallions generally are considered to lack the courage required to compete at the top level, and because the horse takes a number of years to reach its peak, choosing proven sires is a problem. The predominantly TB Irish sports horse and the relatively larger-boned New Zealand and Australian TBs are sought after.

Event horses normally commence dressage and show jumping training at 4 years of age and start competing in prenovice and novice One Day Events from the age of 5. Depending on the horse's ability and rider's skill and patience, a horse usually competes in its first (graded as a CCI* or CCI**) Three Day Event at 6 to 7 years of age. A substantial proportion of horses do not have the ability, courage, or physical durability to proceed beyond the CCI** or CCI*** level to the top grade of CCI****.

INFLUENCE OF THE SPORT ON LAMENESS

Event horses are generally skeletally mature when they commence training and are not trained at the same speed or intensity as racehorses. They therefore have different patterns of injury, although most of the problems are still related to training. Primary long bone pathological conditions are rare. Soft tissue injuries such as tendonitis are common and often career limiting. The amount of endurance training necessary produces repeated cyclic loading, and problems such as osteoarthritis (OA) are common. The other subset of event horse injuries is acute traumatic injuries sustained during competition. Because the horses are jumping large fixed obstacles at speed, they are prone to falls and to direct traumatic fractures. The short format does not seem to have led to a dramatic difference in the type or incidence of injuries. Horses may tolerate low-grade soft injuries better than with the long format, and in the long run there might be a decrease in the incidence of injuries.

Fence design has changed in recent years. Square-shaped fences are avoided, and rounded top contours are now more common. These fences give horses more leeway to correct mistakes and cause less severe direct impact trauma. The fences may be 1.2 to 1.4 m high, with a 2-m spread and a 2-m drop, so substantial strain can be placed on the supporting structures of the limbs on landing. The quality of the terrain also appears to have an important impact on the incidence of lameness problems. The competitions are run predominantly on turf, the nature of which depends on the soil type, local weather, and management factors. At the lower level, financial constraints generally preclude much improvement on the quality of the ground, but some of the top events try to maintain a permanent track that is tended carefully.

The prolonged period and intensity of training required for horses to reach an elite level means that those horses not metabolically or physically suited to the sport are selected out. For instance, few elite horses have recurrent exertional rhabdomyolysis or navicular syndrome. Three

Day Events are regulated by the Fédération Équestre Internationale. A strict medication control program is enforced and permits only emergency medication at the competition after official veterinary approval or the use of a small number of permitted forms of medication, including antibiotics, rehydration fluids, and preparations for treating gastric ulcers.

TRAINING METHODS

Event horses train in all three disciplines, with the actual methods varying greatly among riders. A complete description of training methods is available elsewhere.¹ Most competing horses have natural cross-country ability, so little time generally is spent on training for this, because the progression of competitions provides sufficient experience. Event horses normally are selected for natural jumping action, but jumping technique during the cross-country phase is different from that needed for show jumping. Therefore event horses may not be as careful when show jumping and can have a tendency to touch poles. Most event horses are show jumped regularly, especially during the off season. The event horse's weakest link is usually the dressage phase. The movements required are no more than a medium level of pure dressage, but the different breeding and level of fitness of these horses means that the major challenge can be to control the horse's temperament. Most of the skills training revolves around dressage, and a high standard now is required to be competitive at the top level.

Fitness training is a major component of the preparation for a Three Day Event and is where most orthopedic damage is incurred. The horse is likely to undergo a 3- to 4-month training period for the target Three Day Event. Training methods vary greatly among riders and often depend on local factors such as the availability of hills for trotting or all-weather gallops. Restricting the horse to training solely on an artificial surface is not advisable, because this seems to predispose the horse to injury when the horse actually competes on a natural surface.

Event horses normally receive a 6-week initial period of walking and trotting on the roads, and then commence cantering exercise. Different riders vary in their use of conventional or interval training but usually peak the quantity of work at around three canters of 8 minutes, or shorter if a hill is available. The quality of the work usually is increased closer to the Three Day Event to include faster work. One Day Events are used to monitor the horse's fitness and as additional training. The dressage and jumping training also substantially contributes to the fitness regimen. Older, experienced horses can get to major competitions with relatively few preparatory runs in comparison with less experienced horses, making it easier to manage low-grade injuries.

The majority of riders have not substantially reduced the intensity of their training for short-format competitions. The initial impression was that horses were finishing short-format competitions more tired than at a long-format competition. This was unexpected because of the lower overall effort of the shorter format. It may have been a result of the more intense nature of jumping the same number of fences in a shorter course. There may also have been an element of riders not preparing their horses as

intensively for what was thought to be a less demanding competition. A study comparing cross-country recovery rates at a CCI** in long and short formats showed no significant difference between the two groups.²

CONFORMATION AND LAMENESS

Although the horse's stamp may vary the basic conformation must be correct. Eventing is unforgiving to conformational defects compared with show jumping and dressage. The general principles are the same as for any equine athlete. Serious conformational defects include being back at the knee, having upright pasterns and hocks, and having a moderate or severe toed-out conformation. Of slightly lesser importance are having a long or short back, being over at the knee, or having long, sloping pasterns. Defects such as offset knees and a slight-to-moderate toed-in conformation seem to be less important. A good foot conformation is always desirable, but many event horses have the TB trait of weak feet with collapsed heels.

The prepurchase examination for a young event prospect with hopes of a Three Day Eventing career is likely to be strict. The conformation should be assessed critically at this stage. Although the horse may have sufficient talent, defects in conformation may not allow it to stand up to the 5 or so years of training necessary to reach the top level of the sport. Conversely, it is possible to be more lenient in the interpretation of subtle problems when performing a prepurchase examination on an older, experienced horse. The horse's competitive record should be assessed carefully, because advanced horses are likely to have accumulated wear-and-tear changes during an extended career. Any conformational or subtle soundness queries can be addressed in light of the horse's proven ability to perform its task.

CLINICAL HISTORY

A routine lameness history should be obtained, emphasizing and obtaining the following information:

- Horse's competitive level
- Competition targets and timing, ahead or behind in its fitness schedule
- Previous problems
- Recent competitive or training program
- Current medications
- Prodromal signs
- Onset acute or insidious
- Exact nature of problem (limb swelling, lameness, or poor performance)
- Progression of problem
- Response to treatment

LAMENESS EXAMINATION

My standard approach is described, and the regions requiring particular attention and the most rewarding procedures are outlined for horses with subacute or chronic lameness problems. Care should be taken to palpate all limbs and the back thoroughly, because many concurrent or compensatory injuries can be found that way. Because many problems are subtle, the horse should be examined on a variety of surfaces and at different gaits.

Particular attention should be paid to the feet. The size, shape, and conformation should be assessed in relation to the size and breed of horse. The suitability of the shoe type for that horse should be determined, because farrier preference may have been influenced by fashion. The fit of the shoe should be correlated with stage in the shoeing cycle. Fortunately, the trend is to move away from the traditional problem of shoeing the horse short and tight at the heel. The hoof should be palpated for heat and any cracks or defects. The sole should be pared and hoof testers carefully applied over the entire solar surface, assessing the solar compliance and any pain response. Horses with recurrent bruising associated with soft soles may not have demonstrable pain on examination, but the lack of solar rigidity is clearly evident. Percussion may be helpful in a small proportion of horses. An increased digital pulse amplitude can be helpful in determining the presence of any inflammation in the foot and is especially important if the amplitude is asymmetrical in a limb or between feet. A subtle increase in digital pulse amplitude is best evaluated after trotting the horse in hand on a hard surface.

The horse should be palpated carefully for distention of the distal interphalangeal (DIP) and metacarpophalangeal or metatarsophalangeal (fetlock) joint capsules. The range of joint flexion and any resentment to flexion should be assessed carefully. Particular attention should be paid to the palmar metacarpal structures for presence of subtle, diffuse filling and any discrete swelling, heat, or pain in the tendinous or ligamentous structures. Owners and riders of event horses tend to be thorough in their own palpation of this region and often know the normal contours of their horse well. However, they often are misled by distention of the medial palmar vein or diffuse swelling from a more distal inflammatory lesion.

In the hindlimbs, pain on palpation over the cunean bursa and in response to the Churchill test should be determined. The medial femorotibial and femoropatellar joint capsules should be palpated to detect distention. The muscle tension in the back and hindquarters should be assessed carefully. Trigger points and painful foci should be determined, and the range of spinal flexibility in response to running a blunt object along the back should be assessed.

During the static examination the horse should be assessed for symmetry. The horse's condition and degree of muscling should be assessed in relation to its level of fitness. The freeness of stride, dynamic foot placement, and foot flight arcs should be assessed at the walk. At the trot any head nod and the range of gluteal excursion should be assessed to determine any lameness. Lunging in a circle on a hard surface frequently is used to exacerbate subtle lameness. However, it is also critical to see the horse lunged on a soft surface, a portion of the lameness examination that often is omitted. Different lameness conditions may be evident on different surfaces, and this comparison is valuable. For instance, a horse may have a low-grade concussive distal limb lameness evident when lunged on the hard surface. However, the primary problem may be proximal suspensory desmitis (PSD), pain from which is evident only when the horse is lunged on a soft surface. Notwithstanding the value of evaluating all the lameness problems present, many of these horses have numerous, low-grade sites of pathological conditions to which they have adapted. Evaluating these can be a frustrating business, and it is

important to determine the current problem noticed by a knowledgeable owner or rider. Event horses are often remarkably tolerant of low-grade pain to which they become accommodated compared with dressage horses. Evaluation of the horse while the horse is being ridden can be more difficult, but this form of movement can exacerbate low-grade lameness. Riding may be the only way of observing problems evident during certain movements, such as lack of hindlimb impulsion during a change of gait or when jumping. Seeing the horse ridden by a different, preferably more experienced rider can be helpful in some horses suspected of having back pain or when schooling or behavioral problems are present.

Determining the normal range of soundness is a difficult and contentious issue. Because of age and level of work, most top-level event horses have some degree of orthopedic pathological condition. I prefer to score lameness on a scale of 0 to 10, with 0 being sound and 10 being non-weight bearing. An advanced horse should be sound in the forelimbs when trotted in a straight line, but a large proportion demonstrate a 1 of 10 bilateral forelimb lameness when trotted in a circle on a hard surface. Some horses that are competing satisfactorily may show a greater degree of symmetrical lameness, but asymmetry in lameness may indicate that an important problem exists. Advanced horses can demonstrate up to a 2 of 10 hindlimb lameness when trotted in a straight line, without being penalized for this in a trot-up at a Three Day Event. Many have a 2 to 3 of 10 bilateral hindlimb lameness while circling on a hard surface. Hindlimb lameness evident on soft surfaces is likely to produce lower dressage scores, because the horse will exhibit poor and asymmetrical action.

Flexion tests are useful to exacerbate any subtle lameness problems, but these tests are not specific. Flexion tests can be particularly helpful in evaluating horses with lameness evident only immediately after they have completed an event. These horses can be frustrating, because they are often clinically sound when evaluated subsequently. A persistent positive response to flexion that can be alleviated by diagnostic analgesic techniques is important. Limb protraction, retraction, adduction, and abduction can be helpful in exacerbating upper-limb pain. Turning the horse in a tight circle can be used to assess coordination and flexibility. The range of cervical movement is assessed by observing the horse reach for food (voluntary movement) and by manual manipulation (forced movement). Many horses can cheat and reach the flank by rotation of the upper cervical region, rather than by full lateral flexion of the entire neck.

Different considerations apply when examining the horse with a history of an acute, severe lameness, usually after the cross-country phase of a competition. A comprehensive evaluation of an acutely lame horse must be performed (see Chapter 13) and is described in detail elsewhere.³ Unfortunately, localizing signs may be minimal, the horse may be in cardiovascular shock, and initial efforts must be directed at providing support to the horse and the suspected region of injury. Fractures are caused most commonly by external trauma. Particular attention should be paid to the shoulder region for signs of fracture of the supraglenoid tubercle of the scapula and to the stifle for effusion or periaricular swelling associated with patellar or other fractures. Soft tissue injuries such as severe suspensory

desmitis or superficial digital flexor (SDF) tendonitis may cause acute, severe lameness.

DIAGNOSTIC ANALGESIA

Diagnostic analgesia is an important tool in lameness diagnosis in event horses. Because the horse may have many palpable abnormalities, differential diagnosis is important. However, no localizing clinical signs may be apparent, and diagnostic analgesia is critical to identifying the painful region. Specific treatment can be given if a problem is identified accurately. A positive response to intraarticular analgesia usually means a horse is likely to respond to intraarticular medication, leading to a quicker return to work. In horses with lameness problems too subtle for accurate interpretation of diagnostic blocks, intraarticular administration of corticosteroids may be useful to assess the long-term response to treatment. Even with experienced riders this method of management can have a placebo effect, because the rider may desire for the problem to be veterinary rather than from schooling.

Perineural and intrasynovial analgesic techniques are used commonly. Intraarticular analgesia is particularly helpful because many problems are joint related, and a quick and definitive diagnosis can be achieved. Owners greatly resist clipping of the hair during the competition season, and clipping is not necessary in fine-coated animals if a thorough scrub is performed. The preferred techniques for the most commonly performed blocks are described subsequently.

The palmar digital nerve block should be performed as far distal as possible, angling the needle axially and distally to the cartilages of the foot. Separate medial and lateral blocks may be helpful to localize the pain to a specific heel. Blocking the palmar nerves at the level of the fetlock is less likely to desensitize the fetlock joint with a block performed just below the base of the proximal sesamoid bones (PSBs), rather than at the level of the PSBs. The palmar portion of a low four-point block should be performed just proximal to the digital flexor tendon sheath (DFTS) to decrease the risk of proximal migration of local anesthetic solution, taking care to go above or below the communicating branch of the palmar nerves. The lateral palmar nerve block is a satisfactory method of achieving proximal palmar metacarpal analgesia. Because the middle carpal joint is not a likely source of pain in event horses, the risk of confusing pain from this site with that from the origin of the suspensory ligament is minimal.

The DIP joint is injected most easily at a site on the dorsal midline, using a vertically directed needle. Six milliliters or less of local anesthetic solution should be used to decrease the risk of diffusion from the joint. For the fetlock joints I prefer the lateral sesamoidean ligament approach because most horses do not have gross joint distention and the fixed anatomy of this approach is reliable.

In the hindlimbs the DIP, proximal interphalangeal, and metatarsophalangeal joints often are overlooked sources of pain. Perineural analgesia normally starts with plantar blocks performed at the base of the PSBs, followed by a low six-point block if necessary. Analgesia of the proximal plantar metatarsal region can be performed most easily by blocking the lateral plantar nerve 1 cm distal to the tarsometatarsal (TMT) joint. This blocks the nerve

before it branches into the plantar metatarsal nerves and carries a minimal risk of inadvertent penetration of the distoplantar outpouchings of the TMT joint capsule.

IMAGING CONSIDERATIONS

Radiography

Radiography is the mainstay of imaging, but a few special considerations are necessary in event horses. Lateromedial and dorsopalmar radiographs of the digit can be helpful in assessing foot balance. The palmaroproximal-palmarodistal oblique image often is underused in assessing subtle pathological conditions of the navicular bone and the palmar processes of the distal phalanx. Some fractures of the distal phalanx are only detectable in this radiographic image. The flexed cranioproximal-craniodistal image of the stifle is especially valuable for assessing the medial aspect of the patella for fractures. It is important to angle the x-ray beam so that the trochlear ridges are not superimposed over the patella, because some fractures or evidence of comminution may otherwise be obscured. A relatively underexposed and undercollimated lateromedial image is also beneficial to detect small, displaced fragments, which otherwise may be missed.

Ultrasonography

Ultrasonographic evaluation of the palmar metacarpal structures is a vital part of the lameness evaluation of an event horse. SDF tendonitis is a common and career-threatening injury, and if the veterinarian has any doubt about even a subtle problem, an ultrasonographic examination should be performed. Even when primary forelimb lameness is located at a distal site, the most important lesion may be a compensatory tendonitis in the contralateral limb.

It is usually not necessary to clip the coat, particularly if the hair is fine, and diagnostic images can be obtained after thorough scrubbing and the liberal application of alcohol and gel. The coat may be clipped to obtain maximal detail if subtle tendonitis needs to be investigated. Clients are often reluctant to have the coat clipped for a precautionary scan during the competitive season, because they perceive that the horse will be flagged as having a problem when it next competes. In my experience, sufficient detail is visible in fine-coated horses without clipping, although the clients are warned that greater image quality can be obtained with clipping, and if the image quality is nondiagnostic, the coat needs to be clipped. Often the difficulty is not in identifying abnormalities within the tendon but in determining the relevance of any changes that are present. Many advanced horses have changes in fiber pattern of the superficial digital flexor tendon (SDFT). Transverse and longitudinal views should be obtained in a systematic fashion. Different focus, gain, and frequency settings optimize evaluation of different structures. The cross-sectional area (CSA) of the SDFT should be obtained routinely, because sequential monitoring of this may allow the early detection of tendonitis. Determining the CSA also assists in assessing the current importance of chronic lesions, which is an important and helpful part of the ultrasonographic examination and should not be omitted.

Ultrasonography also can be helpful in assessing articular and periarticular pathological conditions in structures

such as the patellar ligaments. Examination of the ventral sacroiliac ligaments per rectum also can be valuable when pain in this region is suspected.

Scintigraphy

Nuclear scintigraphy is a useful technique for evaluating some lame event horses. Scintigraphy commonly is used in horses with hindlimb lameness, back problems, multiple limb lameness, and forelimb lameness with an equivocal or negative response to diagnostic analgesia. Image quality can be a concern, because event horses are skeletally mature and the degree of pathological bone conditions is low. Normal bone uptake can be limited, except in horses with acute trauma. Good technique is therefore essential to obtain diagnostic images, and postprocessing techniques, such as using motion-correction software, can be helpful. Case selection is also important, because the more chronic and low-grade the problem, the lower the likelihood of finding an obvious focal region of increased radiopharmaceutical uptake (IRU). Examples of conditions for which scintigraphy can be rewarding include nonlocalized foot pain (pedal osteitis and insertional injury of the deep digital flexor tendon [DDFT] attachment), stress fractures (although these are rare overall), and OA of the thoracolumbar synovial articulations (facet joints).

Normal scintigraphic patterns are described elsewhere.⁴ Regions that commonly have greater radiopharmaceutical (RU) than elsewhere in event horses, but without associated pathological conditions, include the distal phalanx, the subchondral bone of the proximal interphalangeal joint, the subchondral bone of the fifth and sixth cervical and sixth and seventh cervical articulations, and the distal tarsal bones. The distal aspect of the tarsus appears to have active bone remodeling when evaluated scintigraphically, but many event horses do not show lameness or a positive response to either flexion tests or local analgesia. In a study evaluating the accuracy of scintigraphy in horses with confirmed distal hock joint pain, we found a positive predictive value of 0.70 and a negative predictive value of 0.91 for focal IRU.⁵ Because of this high false-positive rate, scintigraphy should be used with thorough clinical examination. Although relying on scintigraphy in fractious horses may be tempting, authenticating the diagnosis using diagnostic analgesia is important.

Thermography

Thermography has been used for more than 30 years but is still a developing diagnostic modality. The technology has improved recently, and thermography units are now affordable. The handheld infrared imaging cameras are particularly attractive. Thermographic imaging provides a sensitive representation of skin surface temperature, but many confounding variables make interpretation of these images difficult. To develop expertise involves a steep learning curve, and considerable amounts of time and experience are necessary to make consistently useful interpretations. Major advantages include that the technique is noninvasive and is performed quickly. Thermography is similar to scintigraphy because it is a physiological rather than an anatomical imaging technique. Given the high prevalence and importance of soft tissue injuries in event horses, thermography has applications in detection and in monitoring response to therapy. Because of low specificity,

Fig. 117-4 • Examples of different thermographic foot patterns (solar images). **A**, This horse has a medial corn, manifested as a focal hot spot (white) (arrow) within an area of increased temperature. **B**, This horse has subacute laminitis, with a pattern of increased heat in the region of the tip of the distal phalanx (arrows).

however, thermography should be used with other imaging techniques.

Thermographic imaging is useful in evaluating foot balance and in differentiating various types of inflammation of the foot (Figure 117-4; Color Plate 10). Examinations before and after exercise are particularly useful for this purpose. Similarly, preexercise and postexercise thermograms are helpful in identifying specific superficial muscle injuries. Accurate identification of local muscle strain permits treatment to be focused on the affected area, with a consequently shortened convalescent period. Thermography is also a useful tool in evaluating neck and back problems, although interpretation is more complex in these regions.

Thermography can be particularly useful in monitoring SDF tendonitis and can be used as part of a routine screening procedure, with regular examinations in the run up to a Three Day Event. Thermography can detect small lesions before clinical signs are evident, or it can be helpful in determining if a chronic lesion is active (Figure 117-5; Color Plate 11). If thermography suggests a lesion is present, then ultrasonographic examination is indicated. During the convalescent phase after injury, regular thermographic screening allows detection of any signs of inflammation in the affected region, as the plane of exercise is increased. Care must be taken to avoid artifacts from bandaging, previous clipping, and topical medication.

Magnetic Resonance Imaging

The increased availability and use of magnetic resonance imaging (MRI) have revolutionized the diagnosis and management of foot lameness in recent years. Diagnostic images can now be obtained in a standing horse, without the risk and expense of general anesthesia. This imaging modality is thus much more likely to be used early in the investigation of a lameness problem (see Chapter 21). In horses with foot lameness with no clinically significant radiological signs nor obvious superficial inflammation or pain, MRI can be helpful. Even if there are no relevant findings, the horse can be managed with corrective farriery

and a relatively early return to exercise once the lameness has subsided, with a greater degree of confidence that there is not an underlying soft tissue injury that will be adversely affected. It can also be helpful in assessing the degree of activity of ultrasonographic findings in more proximal soft tissues, and indeed in detecting lesions that are not evident ultrasonographically. Evidence of bone trauma may be detected that is not radiologically apparent.

SADDLE PRESSURE ANALYSIS

Computerized saddle pressure analysis using a force-sensing array system allows an objective assessment of pressure distribution beneath the saddle (Figure 117-6; Color Plate 12). Poor saddle fit is an important problem in event horses and is discussed elsewhere in greater detail (see page 1132). Computerized saddle pressure analysis is straightforward to perform and is complementary to conventional saddle fitting. By allowing an objective assessment, computerized saddle pressure analysis can be useful to confirm a problem to a rider, owner, or saddler. The better systems allow dynamic assessment of saddle fit at exercise, which is not otherwise possible.

PROCEEDING WITHOUT A DIAGNOSIS

Although a diagnosis can be made in most lame event horses, factors such as the experience level of the veterinarian, the thoroughness of the lameness workup, the number of imaging modalities available, and the nature, severity, and stage of the disease process affect diagnostic ability. If a horse is seen repeatedly on a first-opinion basis, stepping back and reassessing the horse as if from the start is sometimes necessary. It may be necessary to refer the horse for a second opinion or for advanced imaging techniques, such as scintigraphy, if these have not been performed. In some horses the precise diagnosis continues to remain elusive. In horses with obscure forelimb lameness, I routinely perform an ultrasonographic examination of the palmar metacarpal soft tissue structures, because tendonitis

Fig. 117-5 • Palmar thermographic image and subsequent transverse (on the left) and longitudinal ultrasonographic images of the metacarpal region of an advanced event horse 10 days after successfully completing a Three Day Event. The horse was having a routine examination, and no clinical localizing signs were evident in the tendon. The thermogram (*top*) demonstrates a focal hot spot over the distal aspect of the left superficial digital flexor tendon (*arrow*), and the ultrasonographic images reveal a hypoechoic core lesion in the same region.

and desmitis are important and highly prevalent. Serial CSA measurements of the SDFTs should be obtained, because the most relevant problem with an undiagnosed low-grade lameness may be a compensatory tendonitis in another limb. Any evidence of tendonitis indicates that exercise level should be decreased. Similarly, any persistent clinical signs of swelling in the palmar metacarpal structures should prompt a cautious approach. Even in the absence of ultrasonographic changes, mild swelling should alert the veterinarian to the possibility of a subclinical problem with tendonitis or desmitis. It is important not to rely too much on ultrasonography for diagnosis of soft tissue injuries, because early lesions may not be apparent.

Generally in horses with low-grade, undiagnosed lameness the response to a period (a few days to weeks) of rest should be assessed. If the response is poor, then most horses with an undiagnosed, low-grade hindlimb lameness can be continued in work, with or without the use of a systemic nonsteroidal antiinflammatory drug (NSAID) such as phenylbutazone. Greater caution normally is advised in horses with undiagnosed forelimb lameness, because the risk of developing a career-limiting injury with continued exercise is greater compared with similar injuries in the hindlimbs. If a subtle problem persists, then it may be necessary to increase exercise intensity to exacerbate the problem to a point at which diagnostic local analgesia can be performed. If a competition is imminent,

Fig. 117-6 • Computerized saddle pressure analysis images. Cranial is to the left, and left is to the bottom. **A**, This image shows a poorly fitting saddle, with a focal pressure point in the left wither region (arrow). **B**, This image demonstrates failure of a gel pad to alleviate the pressure point and the development of an additional pressure point caudally (arrows).

the owner or rider may apply considerable pressure to treat the most likely problem in the hope of rendering the horse sufficiently sound to compete.

If lameness is severe without initial diagnosis, then the horse should be given box rest, and the workup should be repeated until a diagnosis is achieved. If an upper limb soft tissue problem or a back problem is suspected, then a physiotherapeutic, chiropractic, or osteopathic opinion can be helpful. Although veterinary opinion is divided on the validity and value of these techniques, an owner frustrated by the lack of a veterinary diagnosis is likely to turn to these. Horses with poor performance may have schooling or behavioral problems. Assessment by an experienced and different rider can be helpful.

SHOEING CONSIDERATIONS

Foot problems are a major problem in event horses, and the importance of high-quality farriery in minimizing the incidence of lameness cannot be overemphasized. Regular and good farriery is critical in maintaining good

medial-to-lateral and dorsal-to-palmar (plantar) hoof balance. Types of shoes vary among the traditional fullered hunter-type shoes, continental flat shoes, four-point style shoes, and various types of bar shoes. For routine shoeing the conventional fullered shoe offers the advantage of superior grip. Many farriers prefer the extra width of the flat section shoe, because this shoe is easier to fit, has sufficient width at the heel, and gives extra sole cover. If not applied correctly, flat-section shoes may cause excessive sole pressure in horses with flat feet. Traction devices are necessary if flat section shoes are put on horses working on tarmac. Natural balance shoeing has become popular recently in event horses, but although the technique suits some horses, others may actually develop lameness because of improper shoeing technique. However, the natural balance concept of a more palmar location for the breakover point has been well accepted. Seeing horses shod with the shoe set well back is now common, and quarter clips rather than toe clips are most common. This is helpful in horses with long-toe conformation, OA of the DIP joint, or navicular syndrome. A rolled-toe shoe may give a similar effect, although bringing the breakover point back to the same degree is difficult, and care must be taken to set the shoe back sufficiently.

The most common therapeutic shoe used in event horses is the bar shoe. The egg bar shoe is used commonly to manage horses with navicular syndrome and other causes of palmar foot pain and to provide support in horses with a collapsed heel. Egg bar shoes are heavy if they protrude beyond the heel bulbs and may be pulled off. Shoe loss is an important issue in event horses, more so than in other sports horses. As a compromise the straight bar shoe may provide additional foot stability while reducing the risk of shoe loss. In horses that require egg bar shoes, over-reach boots can be used to reduce the risk of shoe loss, and by using a more palmar point of breakover, the front feet may leave the ground more quickly compared with horses with conventional shoes. In horses with a weak heel or quarter, laminar separation, or focal osteitis of the distal phalanx, an egg bar shoe may provide inadequate support and a heart bar shoe can be beneficial. This shoe is heavy, does not project as far beyond the heel as does the egg bar shoe, and transfers some portion of weight-bearing load to the frog. In horses with pain localized to one heel bulb or quarter, a half bar shoe can provide sufficient support and is lighter than a full heart bar shoe.

Pads are used relatively infrequently in event horses. Although pads may provide short-term benefit in horses with sole pain, they promote excess movement of the clenches and premature shoe loosening. Full pads cause a poor microenvironment of the foot. Packing the soles of the hoof has become popular in recent years because it is thought to protect the soles and to have anticoncussive effects, but without the risk of premature shoe loosening. Modern synthetic hoof repair materials can be beneficial in horses that have lost portions of the hoof wall, because the defect can be filled and shoe nails can be placed subsequently. However, routine use of hoof repair materials to augment hoof wall in horses with poor-quality, cracking, and flaking feet should be discouraged and may even cause the problem to persist. If used, repair material should be removed at the end of the season, and the horse should be turned out without shoes. The foot may break up initially but will grow back stronger without the repair materials.

Fig. 117-7 • Palmar view of horse with single studs, showing the degree of medial-to-lateral imbalance induced when the horse is on a hard surface.

Steel shoes are used routinely, but some riders switch to aluminum shoes at a Three Day Event. The foot must be of sufficient quality to cope with the lower degree of support offered by the more flexible aluminum shoe, and switching is not recommended if the horse has any history of foot-related lameness. Any speed and recovery benefits of the lighter shoes do not appear to be obvious in event horses. Synthetic shoes rarely are used.

Road nails or studs often are used, especially in broad section shoes, to decrease the risk of slipping on the roads during walking and trotting exercise. Improper use of road nails or studs may cause hoof imbalance. If the grip point is positioned near the middle of the foot (rather than near the heel), the foot may rock over this point during weight bearing. Event horses commonly wear studs for competition. Some advocate that a single stud be worn simply on the basis that if the stud is on the outside, the risk of the horse treading on itself is less. With a single stud, the foot can still twist, causing less jarring to the limb overall. Conversely, a single stud severely imbalances the foot, and because the roads and tracks phase of a long-format Three Day Event often includes sections of metaled road or tracks, this could induce excessive strain on the joints ([Figure 117-7](#)). Studs should be avoided for the roads and tracks phase if logistically possible. However, some horses will jump with confidence only if two or more studs per foot are applied. The studs always should be chosen based on ground conditions, and a blunt inside stud decreases problems from tread injury. Care should be taken to avoid positioning a stud hole over an area of defective hoof wall. Horses are normally reshod 1 week before a Three Day Event, because if a horse is pricked or any foot soreness occurs after shoeing, the horse has time for recovery.

TACK CONSIDERATIONS

Saddle fit is of great importance in event horses. Injuries to the withers and back may manifest as poor performance in the dressage or show jumping phases of competition. Different saddles are required for the different disciplines of eventing, predisposing the horse to fitting problems. The

fit of the saddle to the horse is sometimes a secondary consideration to riders, who may have a particular saddle in which they feel secure. Event horses often have high withers, and fitting a saddle is often difficult. Saddle fit can be affected adversely by the tendency of event horses to lose weight dramatically in the run up to a Three Day Event. Therefore a saddle that is fitted 2 weeks before an event can sit too low by competition time. Unfortunately, the use of pads and numnahs to correct poor saddle fit is not effective. Computerized saddle pressure analysis has shown that even gel pads are ineffective in alleviating focal pressure points, and that numnahs and pads placed beneath well-fitting saddles can be detrimental (see [Figure 117-6](#)).⁶ Thick or numerous pads elevate the saddle and put pressure on the midline and over the dorsal spinous processes, a situation that impedes spinal flexibility.

Opinions vary on the benefits of protective leg wear. Tendon boots are used almost universally for the cross-country phase, because the risk of direct traumatic injury to the distal aspect of the limb is high. However, the additional insulation increases the temperature of the distal aspect of the limb. There are theoretical concerns that elevation in temperature could damage tenocytes and predispose the horse to tendonitis, although no clinical evidence indicates that this occurs. Some boots have reinforced sections to give additional protection against speedy cut injuries to the palmar aspect of the tendons, but the large rigid section may rub against the tendons at exercise and cause abrasions. Conversely, some of the flimsy boots do not give sufficient protection against this kind of laceration. Bandages give a greater degree of conformity, but they are more difficult to apply correctly and require inclusion of a reinforcing layer if they are to provide substantial protection. Neither bandages nor boots reduce risk of tendon strain but simply protect against direct trauma.

TEN MOST COMMON LAMENESS CONDITIONS

Some conditions are more common during training, and others are more common at competitions. The overall prevalence is as follows:

1. Thoracolumbar and cervical soreness and restriction
2. Foot soreness (bruising, imbalance, and nail bind)
3. Traumatic osteoarthritis
 - a. Distal interphalangeal joint
 - b. Metacarpophalangeal and metatarsophalangeal joints
 - c. Tarsometatarsal and centrodistal joints
 - d. Proximal interphalangeal joint
4. Superficial digital flexor tendonitis
5. Suspensory desmitis
 - a. Branch desmitis
 - b. Proximal suspensory desmitis
6. External trauma
 - a. Lacerations including overreaching injury
 - b. Penetrations
 - c. Stifle bruising
7. Pain in the sacroiliac region
8. Fractures of the stifle region
9. Other fractures
10. Rhabdomyolysis

DIAGNOSIS AND MANAGEMENT OF LAMENESS

Thoracolumbar and Cervical Soreness and Restriction

Neck and back soreness are common clinical findings in event horses, although they do not always limit performance. Soreness may be secondary to lameness as occurs, for example, when pain on palpation of the brachiocephalicus muscle is found in horses with distally located forelimb lameness. Primary problems may be subtle, and determining the importance of clinical findings can be difficult. To know an individual horse's normal degree of sensitivity and flexibility can be extremely helpful, because any changes can be correlated with the onset of a performance problem. Questioning a knowledgeable owner, groom, or physiotherapist can be helpful. Sometimes the clinical significance of any soreness can be assessed only by the horse's response to treatment.

Event horses are particularly prone to muscle soreness when exercise intensity is varied or increased. Intense dressage training initially causes a transient period of lumbar muscle soreness, especially during the sitting trot. Areas of focal pain and muscle spasm may be easily palpable, but assessing flexibility and range of movement is also important. Radiographs are not helpful in diagnosing the relevance of dorsal spinous process impingement, and clinical signs, scintigraphic examination, and a positive response to local analgesia or treatment are necessary to confirm if a lesion is active and/or causing pain. Ultrasonographic examination can be helpful in diagnosing supraspinous ligament injury. Thermography is helpful in detecting acute soft tissue injuries in the thoracolumbar region (see Chapter 25).

Many horses with neck and back pain respond well to physiotherapy. If range of movement is decreased, then mobilization of the affected region is beneficial (see Chapters 93 to 95), which then can be followed by continued stretching exercises, performed by the owner or rider. Massage is beneficial but yields only temporary improvement. Various modalities such as laser, therapeutic ultrasound, and neuromuscular stimulation can be helpful. Results with extracorporeal shock wave therapy have been

encouraging in some horses. In some horses, chiropractic manipulation is beneficial. Acupuncture also can be effective if performed by an experienced practitioner. Given the range of physiotherapeutic treatment options available, the degree of experience necessary for optimal treatment results, and the nature of these therapeutic modalities, I suggest that veterinarians work with an experienced and qualified therapist. It behooves the veterinarian to be familiar with these techniques, because case selection and palpation skills can improve.

Horses with caudal cervical restriction caused by OA of the synovial articulations (articular facet joints) may show a positive response to intraarticular medication with triamcinolone acetonide (5 mg) injected under ultrasonographic guidance. Each affected facet joint is injected, and the horse is rested for 2 weeks, after which time improvement is normally dramatic. Horses with mild to moderate impingement of the thoracic dorsal spinous processes can be treated successfully using local injection of methylprednisolone acetate (40 mg) and Sarapin (6 mL). The horse is lunged or long reined for 2 weeks and then returned to exercise. The duration of effect can be as short as 6 weeks, but in a large proportion of horses, the problem resolves without repeat medication. Marks provides a review of the various veterinary options in treating back pain.⁷ The importance of management and riding factors in treating these conditions cannot be overemphasized. Rehabilitation and reschooling of horses with moderate-to-severe pain are necessary to build up the local musculature and to develop flexibility.

Foot Soreness (Bruising, Imbalance, and Nail Bind)

Foot soreness is a common clinical problem in event horses. Transient sole bruising is frequent, especially in flat- and thin-soled horses. Foot imbalance predisposes horses to soreness, and medial-to-lateral hoof imbalance is commonly present. In horses with a collapsed heel, pain to hoof testers and corns are commonly found. Horses with persistent foot lameness may have laminar separation or focal osteitis of the distal phalanx, and scintigraphy is helpful in differential diagnosis. Poor foot conformation in many horses can predispose them to nail bind or pricking when shod. Shoes often are pulled off, which can lead to breakup of the wall and further problems with shoe security. Regular, high-quality farriery is more important in maintaining good hoof quality than is the feeding of supplements or use of topical applications. Good stable hygiene is also important. Shoeing aspects have been discussed (see page 1131).

Osteoarthritis

Distal limb joints are especially prone to traumatic joint disease, especially in the forelimb. OA of the DIP joint is most common, followed by that of the metacarpophalangeal joint. OA of the proximal interphalangeal joint is rare. Diagnosis is confirmed by observing a positive response to intraarticular analgesia, effusion or fibrosis, a positive response to flexion, and low-viscosity synovial fluid. Radiographs are often unremarkable in horses with early or low-grade OA. Response to intraarticular medication is normally excellent. Combining hyaluronan with a low dose of corticosteroid such as triamcinolone acetonide (5 mg) produces the greatest therapeutic effect. Hyaluronan alone

produces an inconsistent response, and low doses of triamcinolone acetonide have been shown to be chondroprotective. Medium-viscosity hyaluronan usually is used initially based on economic factors, but high-molecular-weight products may give a greater effect in some horses. Systemic administration of hyaluronan (intravenously) or polysulfated glycosaminoglycan (intramuscularly) is not nearly as effective as is specific intraarticular medication. Systemic medication does not carry the same risk of iatrogenic infection and is easier to administer and so is used frequently as an adjunct therapy. Prophylactic use of systemic therapy frequently is used in horses in the run up to a Three Day Event or to manage those with pathological conditions of numerous joints or generalized stiffness. Feeding of nutraceuticals such as chondroitin sulfate and glucosamine is also common practice. Although in vitro evidence of efficacy is substantial, no convincing clinical studies demonstrate efficacy in vivo. In fact, studies have demonstrated a lack of oral absorption of chondroitin sulfate⁸⁻¹⁰ and glucosamine¹⁰ in horses.

In horses with OA of the DIP and metacarpophalangeal joints that has been unresponsive to medication, and especially with radiological evidence of osteochondral fragmentation, arthroscopic evaluation can be beneficial. Focal areas of cartilage and subchondral bone damage may be identified, and the horse often responds positively to debridement. Access is limited in the DIP joint, but lesions often are found on the extensor process of the distal phalanx.

OA of the TMT and centrodistal joints is not infrequent, but the distal tarsal joints show scintigraphic evidence of remodeling even in normal event horses. Horses with authentic OA of these joints usually respond well to medication with low doses of long-acting corticosteroids (40 mg of methylprednisolone acetate). The condition rarely seems to progress sufficiently to necessitate chemical or surgical arthrodesis.

Superficial Digital Flexor Tendonitis

Although not the commonest lameness problem in event horses, tendonitis is the most substantial cause of wastage¹¹ because of prolonged convalescence and high recurrence rates. Although tendonitis can occur as a single-event injury, especially if the horse falls,¹² stumbles, or trips badly, the condition most commonly results from repetitive cyclic loading. Unlike the suspensory ligament, tendons in adult horses do not strengthen in response to exercise and therefore are prone to develop accumulated microdamage during intense training. This damage can give the prodromal signs of slight filling or heat in the palmar metacarpal structures. The clinical signs of a SDFT strain then may develop acutely after a training canter or competition. For horses to develop subclinical tendonitis after a Three Day Event is not uncommon. The condition may not be apparent during the rest period after the competition but develops into clinical tendonitis when the horse resumes training or competitive work, even after 3 to 6 months. Close monitoring is thus essential, and I recommend routine ultrasonography after each Three Day Event. Ultrasonographic evaluation is important to assess the severity of injury and to determine a prognosis and an appropriate treatment plan. Lesion length and percentage of CSA involvement should be determined. Tendons may increase in CSA up to

10% normally with intense training, but this tends to return to baseline at the end of the season. If ultrasonographic examination is performed soon after injury, the extent of the lesion may not be apparent and severity may be underestimated. Severity of tendon damage is assessed most accurately 1 to 4 weeks after injury.

Initial treatment of event horses with SDF tendonitis is aimed at limiting inflammation and preventing any further tendon damage. The horse should be given box rest for 2 to 4 weeks, and antiinflammatory therapy should be commenced. Systemic NSAIDs appear to decrease swelling and pain, and no evidence indicates that they impede healing. Conversely, prolonged corticosteroid administration may interfere with fibroplasia, although a single systemic dose helps decrease inflammation without any apparent detrimental effects.

Support bandages or firm stable bandages should be applied for the first few weeks to reduce swelling. Topical dimethyl sulfoxide can be useful to decrease inflammation early after injury but should not be used for more than 5 days, because it can weaken collagen fibers and blister the skin. Local treatment with cold water hosing and ice application is beneficial while the signs of acute inflammation persist. For horses with mild-to-moderate injuries, the benefits of being able to perform local therapy seem to outweigh the greater external support that can be provided by application of a Robert Jones bandage.

In horses with severe SDF tendonitis in which loss of support (sinking) of the metacarpophalangeal joint has occurred, external support using a Robert Jones bandage is recommended. A heel wedge should be applied if the horse is severely lame. Heel elevation theoretically does not decrease load on the SDFT but appears to provide analgesia to horses that stand with the heel off the ground. In horses with severe breakdown injury, support with a proprietary splint, such as a Kimzey Leg Saver (Kimzey, Woodland, California, United States) is recommended.

Controlled exercise, to encourage development of a longitudinal fiber pattern but without placing excessive load on the tendon to damage the healing fibers, is the mainstay of recuperation. Serial ultrasonographic examinations are helpful to determine the appropriate rate of progress and the response to increasing exercise. After the period of box rest, walking in hand normally is commenced. Mechanical horse walkers appear detrimental in the early stages of healing, because constant turning places excessive load on a weak tendon. However, such walkers are extremely helpful after the initial 4 to 6 weeks of walking in hand, when duration of walking is increased. A major problem during this stage is degree of tolerance shown by the horse to this restricted level of exercise. Many horses are too excitable to be walked safely in hand, but they behave appropriately on a horse walker or if ridden under saddle. Exercise programs must be tailored to account for rider competence and the horse's behavior. Once trotting has been commenced, the horse normally settles down into the exercise regimen.

A large number of treatment options exist for managing event horses with tendonitis. Tendon splitting, usually performed percutaneously in the standing horse, appears beneficial in horses with acute core lesions. Tendon splitting may decompress the core lesion and allow neovascularization but is most effective when performed in the first 10

days after injury. Intralesional injection of hyaluronan or a polysulfated glycosaminoglycan has not proved beneficial. Initial clinical studies investigating intralesionally administered β -aminopropionitrile fumarate unfortunately lacked representative control groups, and a licensed product is no longer available.

Intralesional injections of growth factors have been tried. Insulin-like growth factor-1 (IGF-1) and equine growth hormone, which induces the production of IGF-1, have been studied. I have had success in a small number of horses using transforming growth factor- β (TGF- β) in horses with tendonitis. The drug appears to promote fibroplasia. Although this gives a quicker healing rate and horses have returned to work successfully, whether the expected increase in strength and decrease in elasticity are desirable is theoretically debatable. I have had rewarding results using TGF- β in horses with chronic tendonitis. When ultrasonographic evidence of poor infilling exists, intralesional injection of TGF- β improves fiber pattern, and horses are able to withstand increased exercise intensity. After treatment, some horses have returned to CCI**** level and have completed successfully in up to three events. Platelet-rich plasma (PRP) has been used more for ligamentous than tendinous injuries.

Desmotomy of the accessory ligament of the superficial digital flexor tendon (superior check desmotomy) also can be beneficial in selected horses, and performing the technique tenoscopically carries a much lower risk of postoperative incisional problems. Because of the risk of general anesthesia, I reserve its use for horses with recurrent tendonitis when there are very high owner expectations and for horses in which the ultrasonographic appearance of the SDFT deteriorates inappropriately during the controlled exercise regimen. In a small number of horses in trotting exercise after tendonitis, increased CSA and decreased echogenicity are observed. Even after the plane of exercise is reduced to walking for another 6 to 8 weeks or even longer, the ultrasonographic appearance of the SDFT does not change. After desmotomy, however, these horses tolerate an increased plane of exercise without ultrasonographic deterioration or subsequent recurrence of tendonitis. Because the procedure may increase the risk of suspensory desmitis after surgery, desmotomy should not be used in horses with a concurrent pathological condition of the suspensory apparatus. In a comparative discussion of outcomes for National Hunt horses with tendon injuries treated with different methodologies, superior check ligament desmotomy was the only one to show a significant improvement in outcome in comparison with conservative management, with shock wave therapy, IGF-1, and firing showing only trends toward improved outcomes.¹³

Stem cell therapy has become popular in some quarters (see Chapter 73), but I have not yet seen any clinically significant improvement in outcome and await the results of long-term studies. The expense and the delay in instituting treatment are off-putting. I currently use intralesional injections of bone marrow concentrate, made by processing bone marrow in a commercial system usually used for preparing PRP. This should yield some stem cells as well as growth factors and can be done on an outpatient basis.

Extracorporeal shock wave therapy (ESWT) can be beneficial. Subjectively I have felt that there is an improvement

in the longitudinal fiber pattern. It is particularly useful in horses with mild or chronic tendonitis when there is no clear core lesion for injection.

Systemic medication with a polysulfated glycosaminoglycan is used as an adjunct treatment in horses with tendonitis. Ease of administration and lack of potential complications make such treatment popular, but no evidence indicates that any systemic medication, or feed supplement for that matter, has beneficial effects in tendon healing.

My current approach tends toward combined therapies, as none of the treatments individually have been shown to make any dramatic difference in outcome. Horses with core lesions would be treated with intralesional medication, followed by a course of ESWT and superior check ligament desmotomy if finances and the severity of the lesion justified it.

The total convalescent period depends on severity of initial injury, how well the injury appears to heal determined by ultrasonography, and the degree of compliance with the controlled exercise regimen. In horses with mild tendonitis (subtle loss of fiber pattern and <10% increase in CSA) as few as 6 weeks of walking exercise is sufficient. Horses with loss of fibers and frank tendonitis require a convalescent period of 9 to 15 months. Recurrence rate is less in horses that are given at least a year to recuperate before commencing full work. After tendonitis, many horses can be managed successfully to complete one Three Day Event, but sustaining the horse through a number of Three Day Events without recurrence is more difficult. A small number of horses seem to suffer recurrent clinical signs regardless of management protocol, and these are best restricted to One Day Events, in which they will often then compete successfully for many years.

Suspensory Desmitis

The two main levels of suspensory injury in the Three Day Event horse are branch desmitis and PSD. Midbody desmitis is rare. Suspensory branch desmitis can be considered an occupational disease of event horses. Advanced horses commonly develop inflammation and enlargement of the branches after a Three Day Event, and the condition is often transient with no associated lameness. Viewed by ultrasonography, the branches have periligamentous fibrosis with no areas of obvious hypoechogenicity, although some loss of longitudinal fiber pattern may occur. In many horses this pathological condition is missed or ignored, and the horse is just turned out. Even a short period of controlled exercise often decreases the risk of recurrence, however. Some degree of synovitis of the metacarpophalangeal joint commonly occurs and usually responds favorably to intraarticular medication.

PSD is a common cause of forelimb lameness.¹¹ Lameness may be acute in onset, with inflammation obvious after exercise, or the disease can be insidious without any localizing signs. Diagnostic analgesia is mandatory, and ultrasonographic examination is valuable. Radiographic and scintigraphic examinations are useful adjunct tools. Most horses have true desmitis, although a small number have enthesopathy and associated bone remodeling, with clinically significant IRU and minimal ultrasonographic abnormalities. Most horses respond well to 4 to

9 months of controlled exercise, and no convincing evidence exists that any intralesional medications are beneficial. ESWT is commonly used to treat horses with suspensory desmitis. The analgesic effect may encourage a premature return to full exercise, thus increasing the risk of recurrence, and patience is still required in the rehabilitation of horses with acute injuries. ESWT is useful in horses with chronic, active desmitis, especially those with bone involvement that does not respond appropriately to controlled exercise.

I feel that PSD in hindlimbs is a most important but underdiagnosed condition. Similar to that seen in forelimbs, hindlimb PSD may cause acute or chronic lameness. The prognosis is generally much poorer for horses with hindlimb PSD, however, because of the development of a local compartment syndrome and associated pressure on the plantar metatarsal nerves. Thus most horses remain chronically lame, even after the ligament appears healed on ultrasonographic images. I have had success in treating event horses with persistent, chronic lameness with static or healed ligaments resulting from hindlimb PSD using local infiltration of triamcinolone acetonide (10 mg). Although lameness abates, treatment needs to be repeated at 6-month intervals and may be detrimental to the ligament in the long term. Thus a surgical technique has been developed for use in horses with chronic desmitis that has yielded extremely good results.¹⁴

The surgical technique involves the resection of a 4-cm segment of the common (deep) branch of the plantar metatarsal nerve, distal to its origin from the lateral plantar nerve. This is combined with incision of the fascia (fasciotomy) overlying the origin of the suspensory ligament. This technique combines decompression with analgesia and has allowed horses to return to a normal level of work within 3 months. The horses are restricted to walking only for the first month, after which time turnout and ascending exercise are permitted. I have operated on hundreds of horses, with a long-term success rate of around 75% and a low risk of more extensive suspensory ligament damage developing.

External Trauma

Event horses are prone to traumatic lacerations during competition, the most common being overreach injuries to the heel bulbs and skin abrasions and lacerations, particularly to the carpus and stifles.¹¹ Standard principles of treatment apply, although owners often apply pressure to minimize healing time during the competition season. Aggressive early treatment is advised, and horses with deep foot or pastern wounds should be managed with a fiberglass cast for 10 to 14 days, a treatment that may shorten the convalescent period. Wounds should be assessed carefully for synovial penetrations. Thorn penetrations from brush or hedge fences can lead to infectious arthritis of the carpal or stifle joints, with only minimal clinical signs evident initially.

Direct trauma from jumping solid fences is common. Trauma directly over bone can lead to a severe, transient lameness. Acute lameness from this type of bone bruising can be difficult to differentiate from a fracture on an initial clinical examination. Trauma over the soft tissues may lead to the development of a considerable hematoma or

edema, so local cold and pressure are indicated in the early stages.

Pain in the Sacroiliac Region

A low-grade form of sacroiliac disease is common in event horses and is manifest as a loss of impulsion and scope when jumping, with a reduced hindfoot flight arc. Most advanced event horses have bony pelvic asymmetry when critically assessed. Clinical signs include pain on palpation around the tubera sacrale and resentment of gentle lateral rocking action when the horse is in a weight-bearing position, with the opposite hindlimb held up. Often, associated muscle soreness and spasm are present in the surrounding musculature, notably the middle gluteal muscle. Most of these horses appear to have sacroiliac joint instability, but minimal evidence of IRU is seen on scintigraphic examination. Clinical signs can be localized by assessing the response to infiltration of local anesthetic solution around the dorsal aspect of the sacroiliac joint, using a spinal needle angled ventrocraniolaterally from just caudal to the opposite tuber sacrale. Ultrasonographic evaluation of the ventral sacroiliac ligaments per rectum also can be helpful to localize any pathological abnormality. The condition usually occurs when the horse is unfit and being brought into work or when the plane of exercise is increased. Sacroiliac pain often is self-limiting because the musculature increases as the plane of exercise increases and stabilizes the sacroiliac joint. Administering a systemic NSAID such as phenylbutazone helps the horse work through the period of lameness. Physiotherapy can assist in treating the local muscle spasm, and some horses improve with chiropractic or osteopathic manipulation. Horses with refractory pain sometimes improve after the local infiltration of methylprednisolone acetate (120 mg) or a sclerosing agent (e.g., P2G Solution [50 mL], Martindale Pharmaceuticals, Romford, United Kingdom), using the same approach as for local analgesia. Horses are continued in the same plane of work, and improvement normally is reported within a week. The duration of response varies, and some horses do not require repeat treatments.

Fractures in the Stifle Region

Fractures of the patella are common in event horses,¹⁵ and the imaging aspects have already been discussed. For medial fractures, surgical removal offers the best prognosis. The original surgical description is for an incision 15 to 25 cm in length, but I prefer to use arthroscopic guidance, enabling me to create a minimal surgical incision (5 to 7 cm) centered directly over the fragment. This is satisfactory for small fragments and also allows for thorough evaluation of the femoropatellar joint and easy removal of any loose fragments.

Other Fractures

Fractures caused by direct trauma of the distal phalanx and second and fourth metacarpal bones are not uncommon. Occasionally, condylar fractures of the third metacarpal or metatarsal bones or sagittal fractures of the proximal phalanx occur during training or competition, although they are rare. The standard considerations apply for evaluation and treatment. Vertebral or upper limb fractures can occur after a fall, and the initial evaluation can be complicated by adrenaline dominance.

Rhabdomyolysis

Recurrent rhabdomyolysis is relatively rare in advanced-level horses, because horses prone to this disease are selected out at the lower levels. Sporadic episodes are common at Three Day Events, however. Many potential trigger factors exist, including the stress of travel, stabling away from home, the competition itself, dehydration, climate changes, electrolyte imbalance, and dietary changes. I have noted a particularly high incidence in horses that were switched to haylage products immediately before a competition. This practice is done frequently because of the greater convenience of the small, packaged bales. A period of at least 4 to 6 weeks is recommended to allow adaptation to the new diet. The clinical manifestations at a Three Day Event can vary from collapse and recumbency on the roads and tracks phase in long-format competition to slight stiffness developing many hours after the completion of the cross-country phase of either short- or long-format competition.

To reduce the risk of rhabdomyolysis, attention should be paid to avoiding the trigger factors. Vitamin E levels are frequently low in event horse diets. Many commercial electrolyte preparations do not contain sufficient quantities of salt, and horses may be at risk if owners follow manufacturers' recommendations. Routine blood sampling to monitor the muscle-derived enzymes aspartate transaminase and creatine kinase is performed frequently, but considerable fluctuation in asymptomatic event horses can occur,¹⁶ making interpretation difficult. This variation tends to decrease as horses become fitter, as the muscle cells appear less leaky. With the recognition of polysaccharide storage myopathy as a cause of rhabdomyolysis, some event horses have been successfully managed on a diet high in fat and low in soluble carbohydrates, although actual diagnosis is difficult to confirm.

PREVENTION OF LAMENESS

When considering the time involved to train a horse to the top level and the potential for a long athletic career, preventing lameness is especially desirable in event horses. However, many important factors are beyond the veterinarian's influence. The number and frequency of competitions, having the opportunity to choose events with good going and an appropriate riding surface, and a high standard of riding ability are factors difficult to control. The veterinarian may be able to assist with other factors such as a high standard of farriery and optimizing training programs. Regular veterinary monitoring can be valuable by allowing the early detection and treatment of any lameness problems. Monitoring for incipient SDF tendonitis by performing periodic clinical examinations, using thermographic and ultrasonographic examinations, and monitoring serum markers of tendonitis can be useful. Serial determination of markers such as cartilage oligomeric matrix protein (COMP) holds promise. Initial studies have shown that COMP increases as training intensity increases, and higher COMP levels are found in horses that subsequently developed SDF tendonitis.¹⁷ The concurrent use of all of these maximizes the veterinarian's ability to detect subclinical tendonitis.

Many medications and supplements are sold with the aim of decreasing the risk of orthopedic disease. In racehorses, intramuscularly administered polysulfated glycosaminoglycan and intravenously administered hyaluronan have been shown to decrease the number of races missed, although the incidence of injuries was not decreased. Thus these drugs seem to be acting as antiinflammatory rather than as disease-modifying agents. Many commercial feed supplements are available but have unproven efficacy and variable and uncertain composition.

Chapter 118

Lameness in Endurance Horses

Martha M. Misheff

EVOLUTION OF ENDURANCE

Modern endurance is the most rapidly evolving equine sport. It has its roots in the long distance races of the ancient Bedouin across the desert. Later British and American cavalry used endurance tests as part of their military training, and nineteenth century Austrians had a Vienna to Budapest ride. Despite this long history, organized endurance riding is a young sport. The first modern endurance ride, the 100-mile (160-km) Tevis Cup from Nevada to California, has been run every year since 1955. The Tom Quilty Gold Cup, a prestigious 100-mile endurance race named for its founder, was established in 1966 and is held

every year in a different part of Australia. The oldest endurance organization, the American Endurance Ride Conference, has been in existence only since 1972. Since 1984, all international endurance competitions have been held under the auspices of the Fédération Équestre Internationale (FEI). The Endurance World Championships are held every 2 years in a different host country, and endurance is now the fastest growing FEI sport. More countries participate in international endurance championships than in the international championships of any other FEI discipline.

DESCRIPTION OF THE SPORT

The FEI Rules for Endurance describe the sport as a test of "the competitor's ability to safely manage the stamina and fitness of the horse over an endurance course in a competition against the track, the distance, the climate, the terrain and the clock." It is the clock, however, that determines the winner because the winner is the competitor who completes the course in the shortest time and passes the final veterinary inspection and forensic testing. As the sport of endurance has grown, it has come under intense scrutiny with regard to equine welfare. In addition, there is a great deal of debate within the endurance community

as to whether the more media- and spectator-friendly events favoring increasing speeds over shorter distances (120 km) are preferable to the more traditional sport of slower speeds over longer distances and more challenging terrain. In March 2008, an Endurance World Forum was held in Paris to discuss these and other concerns, and a task force was appointed to revamp current rules governing the sport. The new rules went into effect in 2009; the current championship distance remains unchanged at 160 km (100 miles). The 2008 Endurance World Championships in Malaysia marked the first time that this event was internationally televised.

Each country has its own National Federation, and national competitions may be run under national rules. All international and championship competitions are run under FEI rules, and there are rigorous qualification requirements that must be met to participate. Concours de Raid d'Endurance International (CEI) competitions are divided into 4-star (championship level) through 1-star (low-level) events, depending on the distance covered and age requirements of the horse. Horses must be at least 5 years of age to compete in qualifying events, with age requirements increasing through the star rating. Horses must be at least 8 years of age to compete in championships and CEI 4-star competitions.

VETERINARY CONTROLS

Veterinary controls are an integral part of endurance events, and horses must undergo and pass an initial veterinary inspection and subsequent inspections after each phase of the competition. The total distance of the ride is divided into segments of 20 to 40 km, usually laid out in a cloverleaf pattern with a central Vet Gate area. After riding each section, the competitor must pass the Vet Gate or veterinary checkpoint, where panels of veterinarians evaluate horses for lameness and metabolic criteria. The heart rate must be at or less than 64 beats per minute (bpm) within 20 minutes of arrival from the course to each Vet Gate and within 30 minutes of arrival to the final inspection after crossing the finish line. FEI rules allow the Veterinary Commission the latitude to lower the heart rate criterion if extreme weather conditions are deemed severe enough to warrant it.

The time is taken when the competitor comes in off the course into the crewing area. The competitor has 20 minutes in which to "clock in" to the Vet Gate, or the horse will be eliminated on a time penalty. Heart rate decreases to less than 64 bpm within 1 to 3 minutes of arrival in most elite endurance horses. The time is recorded again when the horse enters the Vet Gate. There is a mandatory hold time after each phase of the competition, which begins from the time of entry into the Vet Gate. Therefore speed of entry into the Vet Gate is a critical opportunity to gain time. If the horse's heart rate is higher than 64 bpm on initial inspection he is "spun" or required to go out of the Vet Gate and return for a reinspection when the heart rate meets the 64-bpm criterion. A horse is permitted one reinspection within the 20-minute time limit at the Vet Gates, but no second chance to meet the heart rate requirement is permitted at the finish. Intensive crewing (rapid cooling with copious amounts of ice water) is common at high-level competitions, and top-level horses generally

come in off the course, have saddles removed, are cooled, have the heart rates checked, and go directly into the Vet Gate. Most championship venues have instituted digital heart rate monitors on which the heart rate for each horse is publically displayed at the end of the trotting lane. A second heart rate is measured by direct auscultation 1 minute after the commencement of a 40-meter trot, and the difference between the first and second heart rates is calculated. This is known as the cardiac recovery index (CRI) or Ridgway Test, after Dr. Kerry Ridgway. Although not a criterion for elimination in and of itself, a positive CRI, in which the second heart rate is elevated more than several beats above the first one, is an indication that the horse merits further evaluation. Other metabolic parameters, such as mucous membrane color, capillary refill time, skin turgor, and auscultable intestinal borborygmi, are checked and recorded. The presence of any saddle sores, girth rubs, or biting lesions is also noted. A heart rate above the maximum allowed, injury, or "consistently apparent" lameness are grounds for elimination. Synchronous diaphragmatic flutter is a common condition in endurance horses and may be grounds for elimination if other metabolic abnormalities are concurrently present. Time-keeping systems for arrival from and departure to the course are automated at high-level events, with riders presenting a digitized "slash card" at timing checkpoints. After passing the veterinary examination, the horse is returned to the crewing area, where it is fed, groomed, and watered before called to return to the course. The horse is not permitted to leave the exit gate until the hold time for each phase is completed. A computerized record of the competitor position, exit time, time taken for the horse to present, and average speed is available at each Vet Gate and at the finish. Endurance horses are not permitted to compete on performance-enhancing medication, and medication control programs are in place to test for substances that are not permitted, in accordance with FEI rules for all equestrian disciplines.

Although national competitions may use the same veterinarians for control and treatment, FEI competitions require separate veterinarians dedicated to each. There are specific requirements regarding the number of commission and treatment veterinarians per number of competitors according to the star rating of the competition. Typically, a horse that is eliminated by a control (Commission) veterinarian for a lameness or metabolic problem is referred to the treatment veterinarian for further evaluation. If the treatment veterinarian deems that treatment is prudent, it is provided at a field clinic at the ride site, or in some cases the horse is transported to a local referral veterinary clinic or to its home stable for treatment. Team veterinarians are usually so busy with other competitors that have not been eliminated that they are happy to have the assistance of the treatment veterinarian. However, it is important that treatment and team veterinarians closely liaise with one another to provide the best possible care. Ride site clinics at large venues or championships offer sophisticated treatment (e.g., blood analysis, fluid therapy, digital radiography, ultrasonography, electrocardiography, endoscopy), and only those horses that require continued care, further diagnostics, or surgical treatment are referred.

Top-level international modern endurance is an extreme sport. Competitors and experienced endurance

veterinarians recognize that proactive provision of post-competition fluid therapy is beneficial in rapidly returning the horse to normal hydration and homeostasis. In my opinion, fluid therapy should not be withheld in an effort to reduce "treatment rates," and competitors whose horses receive fluid therapy to optimize recovery should not be penalized.

TYPE OF HORSE

Most endurance rides are open to horses of any breed, but horses of Arabian extraction are most popularly used for endurance riding because they have light build and stamina for long distance rides. Larger, heavier framed horses are less able to sustain the speed required over the distances traveled. Endurance horses, compared with other athletic horses, tend to be small and light, although in the past 10 years there has been a trend toward taller more robust Anglo-Arab types. Like human marathon runners, good endurance horses tend to be ectomorphs, but speed, cardiac recovery capacity (the ability to rapidly decrease the heart rate after a fast gallop over long distances), and conformation that is likely to withstand the pressure of the demands to which endurance horses are subjected are currently the most sought-after qualities.

TRAINING METHODS AND COMPETITION SPEEDS

Training methods differ considerably among trainers, but most would agree that it takes 2 to 3 years of training to make a good endurance horse. Training distance and frequency depend largely on individual circumstances (terrain, weather, availability of pasture, or turn-out paddocks), but most regularly competing endurance horses are ridden 6 days a week. A typical program might include daily rides of 10 to 20 km, with weekly or 10-day interval 30- to 80-km rides. Horses are ridden at a walk, trot, and canter, with the proportion of the time spent at each gait varying considerably. Horses being prepared for a 100- to 160-km ride will usually perform a 60- to 80-km training ride on at least two occasions before competition. New qualification requirements mandate that horses complete successive rides at lesser distances before being permitted to compete at the next increased distance level. Overtraining of endurance horses tends to be more of a problem than undertraining, particularly by novice trainers.

Endurance competition has rapidly evolved from amateur operations where the same person owned, trained, and rode the same horse for many years, competing for pleasure, with small prizes in kind, to large stables with numerous horses run by professional trainers competing for international recognition, luxury automobiles, and hundreds of thousands of dollars in prize money. The value of a horse winning or running successfully in a prestigious international competition increases exponentially. Speeds at high-profile rides over mountainous terrain have not substantially changed, but as the sport has continued to develop, speeds of competition over flat terrain have increased dramatically. Essentially, at the highest levels the sport has changed from endurance riding to endurance racing. The winner of the 2008 World Championship in Malaysia averaged 18 km/h (5 m/sec) for 160 km, at night,

in a torrential downpour, and with high humidity. A world record time for 160 km of 6 hours, 28 minutes, 28 seconds riding time was set in January 2008. Although the total average speed for all phases was 24.71 km/h (6.86 m/sec), the final 19-km loop was covered at an average speed of 30.29 km/h (8.41 m/sec). It must be borne in mind that as an average over 19 km, actual speeds for short bursts can be substantially higher. As winning speeds at the classic 160-km distance have increased, speeds at the shorter 120-km and 100-km distance have increased even more. In these races, average speeds for some phases reach more than 36 km/h (10 m/sec), which is the equivalent of an "open gallop." It is not unusual to have flying finishes with fractions of seconds separating finishing places. Ten years ago this would have been unheard of. Opinions differ as to whether this is desirable progress, but from a veterinary standpoint, at rides where speeds are increasing, it means that we are beginning to see more flat-racing types of musculoskeletal injuries, as well as serious metabolic abnormalities. Although water is available on the course every 5 to 8 km, riders competing at distances less than 160 km rarely stop on the course to water their horses. The horses are watered when they come into the crewing area.

COURSE TERRAIN

Endurance horses compete and train over some of the most highly variable terrain of any sports horses, including rocky mountains, through creeks, across sandy deserts, along tarmac, gravel, or dirt roads, and across grassy fields, depending on where the ride is held. Course terrain clearly has a bearing on the type of injury, generally in a straightforward way. Stone-bruised feet and painful joints are more common when horses are worked on hard, rocky ground, whereas ligament and tendon injuries are more often observed in horses worked on soft or sandy ground. Downhill grades, if slippery or taken at speed, tend to produce a plethora of dorsal carpal injuries as a result of falls. A relatively recent innovation is the grading and harrowing of long stretches of the course, much like a racetrack without the cushion. Many large endurance stables now train horses on racetracks. This has resulted in an increase in racing-type fractures and superficial digital flexor tendon (SDFT) injuries.

LAMENESS AND CONFORMATION

Lameness in endurance horses can be divided into three categories involving (1) ligaments or tendons, (2) muscle, or (3) joints, bones, or feet. Lameness affecting endurance horses can also be separated into transient problems that may be cause for elimination on the day of competition but then resolve and more persistent problems that are likely to be recurrent. In the relatively recent past, many endurance horses competed over an 8- to 10-year period, and horses with the most glaring conformation defects tended to weed themselves out by attrition. Developments in the sport, most notably increases in speeds of competition, have paralleled the shortening of the competitive life of top-level endurance horses by several years. Astute veterinary advisors make a concerted effort to avoid young horses with flat, asymmetrical, or contracted feet, major angular limb deformities, offset cannon bones, and long, slack, or

short, upright pasterns because these may contribute to later unsoundness problems.¹ Although poorly conformed horses may be successful in the short term or at less-demanding levels of competition, it is an exceptional poorly conformed horse that stays sound and is successful over the time that it takes to reach championship level.² Flaws that are not extreme may be present without compromising the overall function of the horse but are preferentially avoided when possible. Horses with toe-in conformation appear to be more likely to develop splint exostoses that may impinge on the suspensory ligament (SL), causing desmitis, and horses with recurrent suspensory desmitis are ultimately unsuitable for endurance.

THE LAMENESS EXAMINATION AND PROCEEDING WITHOUT A DIAGNOSIS
